INDEX TO VOLUME IV.

[The Names of the Authors whose writings are abstracted or reviewed in the 'London Medical Record' are given at the head of the List under each Letter.]

- A** BEILLE, M., 563; Abeles, Dr., 561; Abramowski, Dr., 167; Adams, Mr., W., 513; Adams, Z. B., 463; Agnew, Dr., 31; Albu, Dr., 26; Alison, M., 282; Allen, Dr. H., 511, 539; Allis, Dr. O. H., 456; Amussat, M., 570; Andrews, Dr. R., 165; Appenrodt, Dr., 545; Archambault, M., 495; Arlès, M., 471, 503; Arndt, Dr., 156, 397; Arnold, Dr. C. D., 416; Arnold, Dr. J., 60, 253; Ashe, Dr., 225; Ashhurst, Dr. J., 363, 536; Atlee, Dr. W. L., 510; Aubert, M., 463; Audigé, M., 412; Ayer, Dr. J. B., 505; Azam, M., 472
- Abortion: tetanus after (McGaughey), 414
- Abscess: pelvic, drainage in (Bixby), 88; perinephritic in children (Gibney), 259; perityphlitic treated by external opening (Buck), 269; mammary, treatment of (Dugas), 269; postpharyngeal in children (Bókai), 486; (Löwenstamm), 494; multiple, in cellular tissue of infants (Bouchut), 495
- Absorptions: in large intestine (Markwald), 154; from human diaphragm (Rajewsky), 252
- Academy: of Medicine in Paris, proceedings of, 33, 92, 134, 181, 231, 281, 326, 375, 420, 518, 562; member of, 287
- of Sciences in Paris, proceedings of, 34, 94, 136, 182, 232, 283, 327, 376, 422, 519, 563
- Acids: influence of on coagulation (Oré), 34
- Acne rosacea: treatment of (Neumann), 555
- Aconite: preparations of (Onimus), 34
- Adenitis: inguinal, simulating femoral hernia (Crussard), 548
- Advertising: medical, in Central Africa, 238
- Æsthesiometer: a new, 473
- Africa: medical advertising in, 238; medical history of campaign in (Gore), *rev.*, 330; cholera epidemic in (Christie), *rev.*, 332; horned men in, 528
- Agaricus bulbosus: influence of on formation of sugar (Oré), 564
- Ague: dropsy after (Deutsch), 256
- Air: microscopic examination of, 325; condensed, physiological action of, 572
- Air-passages: foreign bodies in (Hamilton), 365
- Albuminoid substances: coagulation of (Mathieu and Urbain), 442
- Albuminuria: of pregnant women, milk diet in (Tarnier), 124; in chronic affections (Flecks), 362; amputation during (Terrillon), 472
- Alcohol: form to be administered medicinally (Miller), 119; use of in medicine (Binz), 224; as food and as medicine (Hunt), 513
- Alcoholic delirium: meningo-myelitis with (Weiss), 24
- Alkalies: in diabetes (Ferrand), 212
- Alumina: nitrate of, pruritus of vulva treated by (Gill), 80
- Alveolar process: tumours of (Weinlechner), 516
- American medical plants (Holmes), 223
- Annesia: cauterisation of mucous membrane of pharynx in (Bitot), 563
- Annon: hæmatocele of (Taylor), 126
- Amputation: treatment by the open method (Dennis), 110; changes in spinal cord after (Geuzner), 303; in a case of albuminuria (Terrillon), 471; for disease of knee (Ashhurst), 536
- Amygdalitis: chronic caseous (Bouchut), 283
- Amyl: nitrite of, in intermittent fever (Osgood), 411; physiological action of (Mayer and Friedrich), 444; as an antidote to chloroform (Burrall), 551
- Anæmia: various forms of, and their treatment (Lebert), 289; blood in (Hayem), 378, 422; cerebral, influence on circulation (Couty), 397; essential, 398
- Anæsthesia: by chloral (Bouchut), 21; Bonwill's method of inducing (Hewson), 220; by intravenous injection of chloral (Deneffe and Van Wetter), 260; (Linhart), 378; of larynx before operations, 549
- Anatomical abnormalities (Shepherd), 396
- Aneurism: femoral, treated by direct compression (Brown), 113; internal, successful treatment of, (Tufnell) *rev.*, 139; of aorta, treated by electro-puncture (Fischer), 214; of pulmonary artery (Lebert), 304; traumatic of subclavian artery treated by digital compression (Sinks), 345; of internal carotid in insane (Meyer), 357; of popliteal artery, exceptional situation of, 455; medical and surgical treatment of (Van Buren), 510
- Angina pectoris: treatment of (Sée), 318
- Angioma: periodical turgidity of (Frusci), 365
- Anilin: therapeutic use of (Fiske), 119
- Animals: extinct, 190; cruelty to, 430; voices of, 572
- Ankle-joint: rare injury of (Patruban), 561
- Ankylosis: of cervical vertebræ, 429
- Anorexia (Brugnoli), 481
- Ant-eater, Cape, placentation of (Turner), 542
- Anthrax: abortive treatment of (Guérin), 473
- Anthropology, school of in Paris, 573
- Antiseptic surgery (Hodgen), 506, 508
- Antiseptic treatment of wounds (Kroenlein), *rev.*, 36; in military surgery (Esmarch), 273
- Antiseptic: borax as (Schnitzler), 234; madder-root (De Restaing), 233; sulphurous acid (Balfour), 410; sulphite of soda (Minich), 423
- Ants: language of, 479
- Anus: fissure of, in an infant (Marboux), 454
- Aorta: abdominal, paraplegia from obliteration of (Desnos), 93; thrombosis and embolism of (Chvostek), 215; thoracic, aneurism of, treated by electro-puncture (Fischer), 214
- Aphasia: in general paralysis (Clouston), 23; case of (Bouillaud), 137; with meningitis (Oppler), 306
- Aphonia: chronic nervous, treatment by inhalation of chloroform (De Ridder), 213; case of (Fränkel), 562
- Aphorisms: professional, 575
- Apoplexy: spinal (Goldammer), 92, 306
- Arm: removal of, with scapula and clavicle (Crosby), 112; tubercular meningitis of motor centres of (Raymond), 310
- Army hospitals, 335
- Arnica: local effects of (Fayrer), 116
- Arsenic: in paper-hangings (Brown), 337; malignant lymphoma treated by (Von Winthart), 514
- Arsenious acid and arsenic acid, poisonous qualities compared (Marmé), 374
- Arteries: cerebral, syphilitic degeneration of (Heubner), 50; torsion of (Tillaux), 312; of tibio-tarsal region (Wyeth), 366; abnormalities of (Shepherd), 396
- Arteritis, obliterative (Friedländer), 58
- Artery: pulmonary, ulcerative disease of (Lehmann and Deventer), 14; aneurism of (Lebert), 304; femoral, aneurism of, treated by direct compression (Brown), 113; coronary, blood-current in (Klug), 157; carotid, pulse of (Mendel), 268; subclavian, traumatic aneurism of, treated by digital compression (Sinks), 345; internal carotid, aneurismal changes of in insane (Meyer), 357; popliteal, exceptional situation of aneurism of, 455; anterior coronary, thrombosis of (Doloris), 544; pulmonary, fatty embolism of (Heschl), 560
- Ascites: treated by strychnia (McKie), 224; with cirrhosis of liver in a child (Unterberger), 258
- Asphyxia: during thoracentesis (Tennessee), 214
- Association: British, president of, 429; proceedings of Physiological Section, 468
- French, for Advancement of Science, proceedings of, 470
- Italian Medical, programme of, 430
- Medical, in New Zealand, 528
- Associations, Medical, in Sweden, 574
- Asthma: dyspeptic (Henoch), 325; Langell's remedy for, 460
- Astringents: action on blood-vessels (Rosenstirn), 457
- Ataxy: locomotor, affections of bones and joints in (Raymond), 310; nephritic colic in (Raynaud), 410
- Athetosis (Bernhardt), 405
- Athrepsia (Parrot and Robin), 474
- Atmosphere: effects of increase of pressure of (Pravaz), 40. See Air
- Atrophy: partial, of skin (Taylor), 128
- Atropia: in opium-poisoning in an infant (Morrison), 16; antagonism to morphia (Corona), 341
- Auscultatory percussion (Guéneau de Mussy), 67
- Autopsy at the Hôtel-Dieu, 288
- Avulsion of upper limb (Hendry), 261
- B** ABER, Mr. E. C., 205; Baccelli, Dr., 358; Baginsky, Dr., 134, 323, 561; Balfour, Mr. J., 410; Bamberger, Dr., 560; Baraduc, M., 471; Bardeleben, Dr., 562; Barker, Dr. F., 171, 294; Bardsley, M., 28; Barrett, Dr. E. C., 295; Bartholow, Dr. R., 509; Bastian, Dr. H. C., 422, 423, 519; Bates, Dr. A., 368; Baum, Dr. W., 271; Beard, Dr., 73, 460; Beauregard, M., 49; Becker, Dr., 547; Becquerel, M., 327; Beigel, Dr., 125, 304; Beneke, Dr., 305; Bennett, Dr. E. H., 364; Bennett, Dr. J. D., 224; Bérenger-Féraud, M., 232; Bernard, M. C., 136, 137, 283, 377, 473, 474, 549; Bernhardt, Dr., 32, 405; Bert, M., 66; Bertalot, Dr., 347; Bertholet, Dr. A., 106; Bertolet, Dr. E. M., 297; Bessy, Dr. W. E., 315; Betz, Dr. F., 449; Bezold, Dr. R., 176; Bigelow, Dr. H. J., 111, 367; Bing, Dr. A., 514; Binz, Dr., 224; Birnbaum, Dr., 187; Bitot, M., 563; Bixby, Dr., 88; Blake, Dr. C. J., 512; Blake, Dr. J. G., 416, 551; Bloch, M., 11; Bocheffontaine, M., 354, 422, 453, 474; Böcker, Dr. A., 410; Boeck, Dr. C., 229; Bohm, Dr., 417; Boillot, M. A., 95; Boissarie, Dr., 503; Bókai, Dr., 486; Bompert, Dr., 168; Bonalumi, Dr.,

- 120; Botschetschkaroff, Dr., 156; Bouchardat, M., 411; Boucheron, M., 465; Bouchut, Dr., 21, 283, 495; Bouillaud, M., 137, 327, 420; Bowen, M., 471; Bowditch, Dr., 359, 433; Bowen, Dr., 550; Boyland, Dr., 263; Brakenridge, Dr., 37; Breinig, Dr. P. B., 125; Brencley, Mr. H., 225; Bressgen, Dr., 120; Briddon, Dr., 368; Bristowe, Dr., 564; Broadbent, Dr., 242; Broca, M., 217, 462; Brown, Dr. Bedford, 497; Brown, Dr. Buckminster, 113; Brown, Dr. F. H., 337; Brown, Mr. J. G., 253; Brown-Séquard, Dr., 59, 205, 493; Brugnoli, Dr., 481; Brunet, Dr., 121; Buch, Dr., 198; Buchanan, Dr. W. F., 219; Buck, Dr. A. H., 131, 507; Buck, Dr. G., 262, 316; Buquoy, Dr., 4; Budge, Dr., 539; Budin, Dr., 124; Bulkley, Dr. L. D., 416, 508; Bull, Dr. C. S., 483; Bumstead, Dr. F. J., 510; Bundy, Dr., 550; Burckhardt, Dr., 275; Burckhard-Mérian, Dr., 130; Burdel, Dr. E., 270; Burgl, Dr., 446; Burnett, Dr. C. H., 509; Burrow, Dr., 276; Burrall, Dr., 551; Buresi, Dr., 145; Busch, Dr., 278; Buss, Dr., 193; Butt, Dr., 197; Byford, Dr. W. H., 185, 506
- Bacteria**: nature and relation to disease (Satterthwaite), 12; in fermentation (Pasteur), 474, 519
- Bandages**: plaster of Paris, new method of preparing (Forster), 19
- Baths**: prolonged, in mania (Laehr), 502
- Batrachia**: development of nerves in (Roget), 204
- Bedstead**: an improved, 571
- Bell**: Lady, 574
- Bibulous paper**: topical use of (Fox), 374
- Bile**: action of salts of (Feltz and Ritter), 233; (Brown), 253; secretion of in dog (Rutherford and Vignal), 540
- Bile-duct**: jaundice from congenital malformation of (Lotze), 400; from atresia of (Tibaldi), 401
- Biological**: conference at South Kensington, 284; instruments, 335
- Births**: statistics of in Germany, 180
- Bismuth**: liquor of, in hæmorrhoids and prolapsus ani (Cleveland), 117; subnitrate of in hæmorrhage of typhoid fever (Martineau), 412
- Bladder**: foreign body in (Woods), 74; (Dittel), 178; polypi of (Maas), 260; subpubic extrophy of in a child (Pippingsköld), 401; rupture of (Mason), 407
- Blood**: influence of acids on coagulation of (Oré), 34; function of carbonic acid in coagulation of (Glenard), 34; (Mathieu and Urbain), 183; effect of division of splenic nerves on (Malassez and Picard), 34; pernicious condition of in horses (Signal), 35; migration of corpuscles of (Arnold), 60; dialysis of serum of (Schmidt), 61; transfusion of, 144; variations in amount of (Malassez), 156; sheep's, subcutaneous injection of in insane (Voisin), 170; sugar in (Bernard), 283, 377; relation of coagulation of fibre to corpuscles of (Schmidt), 203; to colourless elements of (Schmidt), 344; in anæmia (Hayem), 378, 422; sudden effusion into labia of pregnant women (Ingham), 414; coagulation of (Mathieu and Urbain), 442; in acute yellow atrophy of liver (Matterstock), 491; flow of through tubes (Haro), 519; influence of curara in corpuscles of (Tarchanoff), 301; normal and asphyxiated, oxidation in (Stroganoff), 539; comparative photographs of, (Gulliver), 541, 573
- Bloodless method**: secondary hæmorrhage after (Esmarch), 277; (Küpper), 548
- Blood-letting**: in Mexico, 144; topical (Mappother), 201
- Blood-pressure**: influence on heart beats (Nawrocki), 155
- Blood-vessels**: cutaneous, inhibitory nerves of (Ostroumoff), 291; action of astringents on (Rosenstirn), 457; dependence of rhythm of heart on variations of (Tschiriew), 488; functions of nerves of (Stricker), 560; lesions of in fractures of the leg (Nepveu), *rev.*, 567
- Bodies**, identification of, 144
- Bone**: regeneration of (Maas), 278; pathological experiments on (Busch), 278
- Bonwill's method** of inducing anæsthesia (Hewson), 220
- Borax**: as an antiseptic, 232
- Bougies**: medicated Eustachian, 131; for treatment of diseases of nose (Catti), 517
- Brain**: electrical stimulation of (Hermann), 9; tumour of (Voelckel), 24; cauterisation of lobes of (Brown-Séquard), 59, 205; apparent hydrophobia from cysticercus in (Neschka), 62; epilepsy with lesion of convolutions (Clouston), 83; localisation of diseases of (Charcot), 93, 302; the ophthalmoscope in injuries of (Panaz), 136, 182; constrained movements in diseases of (Eichhorst), 160; foreign bodies in (Carpenter), 226; caloric action of certain regions of (Eulenberg and Landois), 233; syphilitic disease of (Wood), 246; epilepsy a symptom of syphilitic disease of (Fournier), 264; inebriety after concussion of (Crothers), 449; influence of excitation of in heart-beats (Lepine), 354; effect of faradisation of cortex of (Bochefontaine), 354, 422; functions of hemispheres of (Carville and Duret), 355; topography of (Féré), 356; (Broca), 421; epileptic phenomena in a case of tumour of (De Bovis), 361; movements of (Salathé), 378; localisation of motor centres in (Dupuy), 395; influence of anæmia of on circulation (Couty), 397; hæmorrhage in (Miles), 403; method of staining the (Lewis), 445; of the canidae (Garner), 459; cysticercus in (Mazzoni), 491; alterations in mucous membrane of stomach after lesions of (Brown-Séquard), 493; microscopic study of (Kempner), 507; causes of convulsions in (Meynert), 515; a convulsion of (Heschl), 518
- Bran-bbox**: treatment of fractures by (Bates), 368
- Bread**: aerated, 570
- Breast**: strapping the (Munson), 125; treatment of inflammation and abscess of (Dugas), 269
- Breathing**: by mouth, dangers of (Guye), 130
- Brett's eau-de-vie**, 526
- Bright's disease**: chronic, treatment of, 80
- Bromide of camphor**: antagonism to strychnia (Valenti y Vivo), 459
- Bromide of potassium**: chorea treated with (Goetz), 309; subcutaneous injection of in epilepsy (Frigerio), 458; as a caustic (Peyraud), 473; skin-eruptions from (Pinsker), 559
- Bromide of quinine** (Raymond, Soulez, and Choffé), 487
- Bromide of sodium**: epilepsy treated by (Hollis), 370
- Bromine**: solution of, as dressing, 169
- Bronchitis**: capillary (Ellis), 69
- Broncho-oesophageal muscles** (Cunningham), 154
- Broncho-pneumonia**: intermittent, 94
- Buller, Dr. F.**, 479
- Bullets**: chemical detection of in gunshot wounds (Uhler), 549
- Burns**: treatment of, 170; (Smith), 374; pathology and treatment of (Brown), 497
- Bursæ**: syphilitic affections of (Keyes), 222
- CAMPBELL, Dr. J. A.**, 82; Carpenter, Dr. W. B., 226; Carville, M., 335; Caspary, Dr., 222, 264; Catti, Dr., 517; Cavazzani, Dr., 499; Cazin, Dr. H., 27, 518; Challe, Dr. E., 501; Chambaud, Dr., 552; Charcot, M., 97, 148, 342, 385; Chauveau, M., 1, 34, 94, 135, 136; Chiari, Dr., 231, 517; Chibret, M., 473; Chisholm, Dr., 176; Choffé, M., 487; Christie, Dr. J., 332; Churchill, Dr. F., 269; Chvostek, Dr., 215, 258; Cleeman, Dr., 534; Cleland, Dr. J., 117, 567; Clouston, Dr., 23, 83; Cobbold, Dr. C. W. S., 329; Cohn, Dr. R., 418; Cohnheim, Dr., 448; Colin, M., 93, 134, 448; Collins, Dr. D. F., 493; Colomiatti, Dr., 173, 206; Colvat, M., 473; Conner, Dr., 408; Cornillon, M., 471; Corona, Dr., 343; Corradi, Dr., 165; Courtney, M., 473, 505; Couty, M., 397; Craig, Dr. W., 169; Crawford, Dr., 15, 456, 550; Creighton, Dr. C., 400; Critchett, M., 176; Crombie, Dr., 228; Crosby, Dr. A. M., 112; Crothers, Dr., 349; Crussard, Dr., 548; Cuiquet, Dr., 30; Cumming, Dr. J., 85, 228; Cunningham, Dr., 154; Curie, M., 564; Curschmann, Dr., 542; Cyon, M., 283; Czerny, Dr., 314
- Cæsarean section**: with ovariectomy (Hillas), 25; in cases of fibroid tumour (Cazin), 27; cases of (Bardy-Delisle), 28; (Cohn), 418; application of catgut suture to uterus after (Martin), 277
- Caffeine**: toxicology of (Perretti), 301
- Calculus**: new method of searching for (Van Brabant), 312; causes and geographical distribution of (Mastin), 511
- Calculi**: vesical (Förstheinheim), 321
- Calculus patients**: gout or rheumatism in, after operations (Courtty), 473
- Camphor**: bromide of, antagonism to strychnia (Valenti y Vivo), 459; carbolised (Soulez), 500
- Camphorated ether**: in erysipelas (Cavazzani), 499
- Cancer**: of navel (Wulckow), 64; of cervix uteri impeding delivery (Depaul), 271; post-pharyngeal (Sevestre), 398; of kidneys (Froumüller), 399; of ovary (Golay), 413
- Canidae**: brain of (Garner), 469
- Canthoplasty**: for certain diseases of eye (Agnew), 31
- Carbolic acid**: treatment of acute rheumatism by packing with, 160; cerebral symptoms during injection of pleura with (Walcher), 310; anæsthetic action of (Levis), 315; administration to diabetic subjects before operations (Fischer), 406; inefficiency of as a disinfectant, 501
- Carbolised camphor** (Soulez), 500
- Carbonic acid**: relation of excretion of to bodily temperature (Erler), 251; influence on respiration (Raoult), 328
- Carlsbad**: waters of, in kidney-disease (Flecker), 362
- Carnivorous plants**, 46
- Carotid pulse** (Mendel), 269
- Carpenter, Dr.**, on spiritualism, 576
- Carson, Dr. F.**, 479
- Cartilage**: hyaline, structure of (Baber), 205
- Cartilages**: costal, fracture of (Bennett), 364
- Catalepsy**: cure of (Street), 404
- Cataract**: congenital, and its treatment (Critchett), 176; modification of Von Gräfe's operation for (Galezowski), 472
- Catarrh**: of female genitals in children (Haussmann), 126
- Catgut suture**: application to uterus after Cæsarean section (Martin), 277
- Catheters** for leaving in the bladder (Amussat), *rev.*, 570
- Cateterism**: posterior (Ranke), 407; of ureter (Grünfeld), 516
- Cauterisation**: of erectile tumours (Bigelow), 111; of pharyngeal mucous membrane (Bitot), 563
- Cautery**: actual, prevention of pain after (Levis), 315; galvanic, metrorrhagia treated by, 170; thermic (Paquelin), 328
- Cedar**: red, poisoning by oil of (Holley), 374
- Cells**: ganglionic, nuclei of (Schwalbe), 445
- Cellulitis**: pelvic, diagnosis from hamatocele (Barker), 171
- Cement-substance** of so-called endothelium (Arnold), 253
- Cerebellum**: new formation in (Winter), 23
- Cerebro-spinal diseases**: neuralgia and visceral neuroses in (Teissier), 470
- Cerebro-spinal meningitis**: heat in treatment of (Bennett), 224; in Birmingham, 287; case without symptoms (Paolucci), 493
- Cerebrum**. *See* Brain.
- Cerium**: oxalate of (Mills), 118
- Chancres**: anatomy of (Caspary), 264
- Charité-Annalen**, *rev.*, 95
- Charrière, M. J. F.**, 335
- Chevrel, M.**, 572
- Child**: precocious development in a (Huggins), 126; exophthalmic goitre in a (Chvostek), 258; intestinal obstruction in a (Bauer), 258; cirrhosis of liver and ascites in a (Unterberger), 258; cranial tumours in a, 516
- Children**: diet of (Wilson), 242; perinephritic abscess in (Gibney), 259; tubercular meningitis in (Bertalot), 307; new-born, pemphigus of (Bohn), 417; peritonitis in (Kersch), 453; relapsing fever in (Unterberger), 453; etherisation in (Tripiet), 472; mortality of (Dubert), 473; postpharyngeal abscess (Bökai), 486; (Löwenstamm), 494; treatment of umbilical hernia in (Archambault), 495. *See* Infants
- Chile**: diseases of, 575
- Chloral**: enemata of in chorea (Guyot), 109; pityriasis capitis treated by (Martin), 128; in pruritus of vulva (Gelle), 170; as a dressing (Craig), 160; anæsthesia by intravenous injection of (Deneffe and Van Wetter), 260; (Linhart), 378; tetanus treated by intravenous injection of (Oré), 376; in infantile convulsions (Löwenstamm), 495; local action of (Tizzoni), 499
- Chloroform**: administration of (Reeve), 165; nervous aphonia treated by inhalation of (De Ridder), 213; injection of in sciatica (De Cérenville), 412; nitrite of amyl as an antidote to (Burrall), 551
- Cholera**: and the Mecca pilgrims, 96; causes of (McClellan), 213; Epidemics of in East

Africa (Christie), *rev.* 332; Asiatic, History of (Macnamara), *rev.* 474
Cholestearine (Flint), 508
Chorea: in general paralysis (Clouston), 23; cured by enemata of chloral (Guyot), 109; treatment by ether-spray (Fabry), 213; treated by bromide of potassium (Goetz), 309

 Harper's steam-drift inhaler, 428
 Headache: therapeutics of (Smith), 390
 Hearing: means of testing (Burnett), 509; of school children (Blake), 512; impaired, new means of diagnosis of (Bing), 514
 Heart: position of impulse of in different postures of the body (Ransome and Patchett), 11; functional diseases of (Andrews), 16; influence of disease of in menstruation, pregnancy, and the fœtus (Duroziez), 27; fetal (Cumming), 85, 228; impulse of (Guttman), 109; influence of blood-pressure on beats of (Newrock), 155; (Tschiriew), 488; movements of (Marey), 183; insufficiency of auriculo-ventricular valves of (Widmann), 210; telluric neuralgia of during pregnancy (Burdell), 270; influence of excitation of brain on beats of (Lepine), 354; pistol-shot wound of (Comer), 408; effect of constant current on (Foster and Dew-Smith), 446; effect of excitement of sensory nerves on (Frank), 470; malformations of septa of (Rokitansky), 492; pressure on left ventricle (Stricker), 514; aperture in septum ven-

- tricolorum (Duckworth), 541; rupture of (Doloris), 544.
- Heat: distribution of in febrile diseases (Jacobson), 107; in treatment of cerebro-spinal diseases (Bennett), 224.
- Hemiplegia: case of from cerebral hæmorrhage (Miles), 403.
- Hepatitis: of hot climates (Sachs), 452.
- Hereditary tendencies, intermarriage as a corrective of, 47.
- Hermaphrodite: supposed testicle removed from the vagina of a (Rodgers), 13.
- Hernia: diaphragmatic (Drake), 13; of muscle (Högnischmied), 164; ventral, treatment of (Haddich), 281; umbilical, in children, treatment (Archambault), 495; femoral, inguinal adenitis simulating (Crussard), 548.
- Herpes zoster: etiology of (Kaposi), 173; pathology and treatment of (Bulky), 416; tonsurs in patients treated for favus (Aubert), 463.
- Herpetic effusions of ear causing deafness (Ladreit de Lacharrière), 321.
- Hip-joint: so-called congenital dislocation of (Sayre), 111; shortening of limb from disease of (Viennos), 365; treatment of disease of (Sayre), 511; dislocation of on both sides (Crawford), 550.
- Hordaceous concretions, 471.
- Horned men in Africa, 528.
- Hospital: London, appointment at, 287; new, in Paris, 479; military at Nish, 528.
- Hospitals, prize for essay on mortality in, 46; diseases germinated in, 573.
- Hot climates: hepatitis of (Sachs), 452.
- Hôtel-Dieu: an autopsy at, 238.
- Humerus: peculiar forms of dislocation of (Shapleigh and Hamilton), 219; unrecognized dislocations of (Smith), 409; subcoracoid dislocation occurring several times a day (Tillaux), 409.
- Hunting: accidents during (Galezowski), 562.
- Hunyady János waters, 120.
- Huxley, Professor, on evolution, 575.
- Hydatids: of liver (Seligsohn), 254.
- Hydrobromate. See Bromide.
- Hydrocele: treatment of (Volkman), 163.
- Hydrophobia: apparent, depending on cysticercus in the brain (Maschka), 63; treatment of by xanthium spinosum (Gryzmala), 266; supposed, treated with strychnia and woorara (Watson), 438.
- Hygiene and religion, 479; in Russian schools of medicine, 480.
- Hygroma: prepatellar, treatment of (Volkman), 313.
- Hyosciamine: therapeutic action of (Lawson), 372.
- Hypnotic: lactic acid as a (Senator), 419.
- Hypodermic: alimentation (Whittaker), 163; injections, use of salicylic acid in preparation of (Limousin), 319.
- Hysterotomy: removal of uterine fibroids by (Hegar), 227.
- I**NGHAM, Dr., 414; Israel, Dr., 418.
- Ichthyosis: congenital (Löcherer), 454.
- Ileum: congenital stenosis of (Pippingsköld), 401.
- Induced current: use of in dilatation of stomach (Fürstner), 168.
- Inebriates: treatment of (Harris), 293.
- Inebriety: from physical and mental lesions (Crothers), 349.
- Infant: use of atropia in opium poisoning in an (Morrison), 16; precocious development in an (Huggins), 126; sarcoma of kidney in an (Baginsky), 323; menstruation in an (Arnold), 416; intussusception in an (Senator), 419; fissure of anus in an (Mabboux), 454.
- Infants: normal digestion in (Wegscheider), 11; anæsthesia by chloral in (Bouchut), 31; newly born, function of cerebrum in (Soltmann), 84; rupture of liver in (Pincus), 87; mortality in Berlin (Baginsky), 134; in Egypt, 238; new-born, deglutition in (Houze de l'Aulnoit), 472; iodine in therapeutics of (Simon), 494; multiple abscesses of cellular tissue in (Bouchut), 495; chloral in convulsions of (Löwenstamm), 495; feeding of (Magne), 518; (Hervieux), 563; (Devergie), 563; purpura hæmorrhagica in, (Appenrodt), 545. See Children.
- Infectious diseases: changes in labyrinth in (Moos), 556.
- Inhaler: Harper's patent steam draft, 428; patent pocket, 526.
- Injection: Hegar's apparatus for (Mader), 179, 230.
- Injury, old, tale of, 46.
- Insane: influence of coloured light on (Ponza), 123; subcutaneous injection of sheep's blood in (Voisin), 170; general paralysis of (Ashe), 225; aneurismal changes of internal carotid in (Meyer), 357; responsibility of the (Ray), 509; chronic, provision for (Nichols), 513.
- Insanity: short attacks of, 82; contagious of (Brunet), 231; relation of intemperance to, 238; hypodermic injection of morphia in (M'Diarmid), 268; after typhoid fever (Hemkes), 502; simulation of by the insane (Hughes), 511.
- Insectivorous plants, 46.
- Instruments, scientific, at South Kensington, 335, 573.
- Intemperance: relation of insanity to, 238.
- Intercostal muscles: action of (Rutherford), 489.
- Intermarriage: a corrective of hereditary tendency, 47.
- Intermaxillary bone: persistence of in human subject (Rougon), 283.
- Interment: Roman method of, 288.
- In testine: large, digestion and absorption in (Markwald), 154; internal strangulation of (Klob), 177.
- Intra-abdominal pressure (Odebrecht), 219.
- Intussusception: in an infant (Senator), 419.
- Iodides: in heart-poisoning (Faure), 564.
- Iodine: brine-springs containing (Roehrig), 1; subcutaneous injection of tincture in glandular swellings (Bonalmi), 120; use of in treatment of diseases of the ear (Ladreit de Lacharrière), 465; in therapeutics of infancy (Simon), 494.
- Iodoform: in vaginismus (Tarnier), 28.
- Ipecacuanha: action of (Rutherford and Vignal), 541.
- Iridin: action of (Rutherford and Vignal), 540.
- Iris: hydraulic movements of (Mosso), 343.
- Iritis: syphilitic, subcutaneous injection of calomel in (Saltini), 464; influence of neuralgia of trigeminus in causing (Bull), 483.
- Iron: acid sulphate of in diphtheria (De Sabatata), 120; saccharated iodate of, in congenital syphilis (Monti), 222; sulphate of, in diphtheria (Fera), 499; dilatation of lacrymal sac treated by injection of perchloride (Spampinati), 558.
- J**ACKSON, Dr. Hughlings, 22, 43; Jackson, Dr. J. B. S., 357; Jackson, Mr. J. R., 114; Jacobs, Dr., 167, 403; Jacobson, Dr., 107, 323; Jahn, Dr., 194; Jerusalemsky, M., 499; Johnson, Dr. C., 506; Jones, Dr. H. M., 175.
- Jaborandi: cure of tetanus by (Bompart), 168.
- Jalap: action of (Rutherford and Vignal), 541.
- Jaundice: epidemic (Klingelhoeffer), 211; mitral bruit in (Gangolphe), 361; slow pulse in (Leggs), 361; from malformation of bile-duct (Lotze), 400; from atresia of bile-duct by cirrhosis of head of pancreas (Tibaldi), 401.
- Jaw, upper, tracheotomy before excision of (Pilcher), 75.
- Joints: affections of in locomotor ataxy (Raymond), 310; treatment of disease of, by extension, 369; mechanism of (Allen), 512; lectures on diseases of (Sayre), *rev.*, 520; operative and conservative surgery of (Ashhurst), 536.
- Journals, new medical, in Ohio, 479.
- Juniper fumigations in skin-diseases (Boeck), 229.

 Nitric acid: *post mortem* appearances in poisoning by (Hjelt), 461
 Nitrobenzol: poisoning by (Stevenson), 320
 Nitrogen: elimination of by kidneys (Fränkel), 67
 Nose: deposition of ova of fly in fossæ of (Buchanan), 219; frostbite of (Riedlanger), 281; decortication of in elephantiasis (Ollier), 421; bougies for treatment of diseases of (Catti), 517

ODEBRECHT, Dr., 26; Ollier, M., 421, 474; Onimus, M., 34; Oppler, Dr., 306; Oré, M., 34, 376, 564; Orth, Dr., 206; Osgood, Dr., 273, 411; Ostroumoff, M., 291; Otis, Dr. F. N., 365; Ott, Dr. I., 12, 61, 458
 Obstetrical Practice, Reminiscences of (Spöndly), *rev.*, 184
 Œsophagotomy: cases of (Gussenbauer), 218; (Cazin), 518
 Œsophagus: foreign bodies in (Cazin), 518; (Stanford), 549; epithelial cast from (Lincoln), 545
 Œleum erigerontis Canadensis: in gonorrhœa (Starke), 267
 Onychia: ulceroosa lurida (Rizzoli), 173
 Ophthalmia: sympathetic, treatment of (Boucheron), 377, 465
 Ophthalmoscope: metric (Giraud-Teulon), 33; use of in injuries of the brain (Panaz), 136; (Giraud-Teulon), 182; construction of (Loring), 286
 Opium: use of atropia in poisoning by, in an infant (Morrison), 16
 Os calais: complete extirpation of (Ollier), 421
 Ossicles of ear: anatomy of (Urbantschitsch), 254
 Ossification: of dorsal muscles (Gibney), 110
 Osteitis: experimental researches on (Busch), 278
 Osteomyelitis: primary infective (Friedmann), 131
 Ova: Development of (Foulis), *rev.*, 185
 Ovariectomy: with Cæsarean section (Hillas), 25; pelvic drainage after (Bixby), 86; case of in agria (Koberle), 90; during septicæmic fever (Peruzzi), 124; menstruation from pedicle after (Prewitt), 229; during pregnancy (Baum), 271; experimental researches on (Wegner), 278
 Ovary: cyst of, spontaneous cure of (Quinby), 27; Structure of (Foulis), *rev.*, 185; differential diagnosis of serous cysts of (Koberle), 269; carcinoma of (Golay), 413; extirpation with uterus (Kimball), 414; absence of (Goelet), 503; removal of (Trenholme), 553
 Ovum: habitual death of (Leopold), 28; retained (Churchill), 269; human (Mayerhofer), 514
 Oxidation in normal and asphyxiated blood (Stroganoff), 539
 Oxygen: in blood at different barometric pressures (Bert), 60

Ozone: action on animal substances (Boillot),
95
Oysters: Portuguese, 573

Pachydermata: placenta of (Dastre), 204
Pachymeningitis: circumscribed (Hardy), 299
Pacinian bodies: in celiac plexus (Genersich),
493

Pain: sulphate of quinine in (Verneuil), 120;
after application of actual cautery, prevention
of (Levis), 315

Pancreas: changes in during digestion
(Heidenhain), 62; jaundice from cirrhosis of
head of (Tibaldi), 401

Paper-hangings: arsenical (Brown), 337

Paracanthosis: thoracic, by the pneumatic aspirator
(Tutschek and Zaggel), 808; cases of
(Hoisel), 359; (Bowditch), 359; of pericardium
(Hardy), 297

Paralysis: general, aphasia and chorea in
(Clouston), 23; acute spinal in adults (Erb),
66; of spinal accessory nerve (Fränkel), 92;
double, of upper limbs (Rosenthal), 177;
general, of insane (Ashe), 225; acute ascending
(Déjérine and Goetz), 404

Paraplegia: diagnosis of (Wood), 64; from
obliteration of abdominal aorta (Desnos), 93;
reflex (Laveran), 207

Parotitis: suppurative, in an infant (Henoch),
419

Parturition: subacute cystitis after (Richardson),
171. See Labour

Patella: operative treatment of enlarged bursa of
(Volkman), 313; transverse fracture of
(Crauford), 456

Pellagra: in Roumania (Scheiber), 229; character of
(Winternitz), 418

Pelvic hæmatocele and pelvic cellulitis, diagnosis of
(Barker), 171

Pelvis: contracted, treatment of (Taylor), 29;
drainage of (Bixby), 88; diagnosis of congestion
of (Guérin), 374; narrow, labour in
(Goodell), 509

Pemphigus: case of (Neumann), 179; acute, of
new-born children (Bohn), 417; alteration
of nervous system in (Déjérine), 423

Pepsin: formation and excretion of (Grützner),
302

Peptones: (Plösz and Györgyai), 60; (Bamberger), 560

Percussion: auscultatory (Gueneau de Mussy),
67

Pericardium: puncture of (Roger), 297

Perineum: laceration of (Goodell), 52, 98;
anatomy of (Allen), 539

Perinephritic abscess: in children (Gibney),
259

Periostitis: diffuse phlegmonous, treatment of
(Duplay and others), 73

Peritoneum: fatty or chylous effusions in
(Quinke), 216

Peritonitis: treatment of by opiates (Loomis),
161; with protrusion of navel (Stitzer), 360;
in children (Kersch), 453; complicating
labour (Ayer), 505

Perityphilitis abscess: with external opening
(Buck), 262

Petroleum: as a dressing for ulcers (Paul), 116

Pewter plate removed from œsophagus (Stanford),
549

Pharmaceutical chemist, a lady, 46

Pharmacopœia: British, Commentary on
(Smith), rev., 524

Pharyngotomy: subhyoidæan, for sarcoma of
gullet (Baum and Rosenbach), 75

Pharynx: cauterisation of (Bitot), 563

Phimosia: relations with diabetes (Bourgade),
471

Photographic revolver, a, 527

Photographs, comparative, of blood,
Phthisis: action of climates in treatment of
(Gourand), 292; syphilitic (Fournier), 308;

temperature in (Schwartz), 393; beech-tar
creosote in expectoration of (Daremborg),
501

Phylloxera, 573

Pilocarpine: action on submaxillary gland of
dog (Langley), 490

Pityriasis: capitis, treated by solution of
chloral (Martineau), 128

Placenta: prævia, treatment of (Davis), 86;
foetal, of pachydermata (Dastre), 204; comparative
anatomy of (Turner), rev., 423;
syphilitic disease of (Ercolani), 462; fatty
degeneration of a cause of abortion (Leale),
462; of Cape ant-eater (Turner), 542

Placental soufflé (Boillaud), 327

Plague: in Mesopotamia (Tholozan), 378

Plants: carnivorous, 46; American medicinal
(Holmes), 223

Plaster of Paris bandages: new method of preparing
(Forster), 19; (Zsigmondy), 231

Plethysmograph, 285

Pleura: chylous or fatty effusions in (Quinke),
216; injection of with carbolic acid, cerebral
symptoms during (Walcher), 310; transmission
of sounds through fluids in (Gueneau de
Mussy), 311; (Bacelli and Valentiner),
358; symptoms of adhesion of (Marten),
401

Pleurisy: with gangrene of lung (Bucquoy),
4; operative treatment of (Ewald), 324;
(Israel), 418

Pleuro-œsophageal muscles (Cunningham), 154

Plexus: cœliac, Pacinian bodies in, (Genersich),
493

Pneumograph, a new, 473

Pneumonia: natural history and relations of
(Sturges), 183

Pneumopericardium traumaticum (Leonbacher),
162

Pneumothorax (Flint), 217

Poisoning: by nitro-benzol (Stevenson), 320;
by arsenical paper-hangings (Brown), 337;
by fungi (Schiff), 339; by arsenic (Marmel),
374; by oil of red cedar (Holley), 374; by
cyanide of potassium (Post), 461; by nitric
acid, *post mortem* appearances in (Hjelt),
461; by lead, iodides in (Faure), 564

Poisons: animal, experiments on (Chauveau),
135; vegetable, sassafras an antidote to
(Lyle), 460

Polyp: nasal (Roth), 179; of urethra (Grünfeld),
230; of male bladder (Maas), 260; of ear
(Ladreit de Lacharrière), 534

Polyuria: hygienic treatment of (Bouchardat),
411

Port wine mark and its obliteration (Squire),
rev., 478

Postpharyngeal abscess in children (Bókai),
486; (Löwenstamm), 494

Potash: bicarbonate of, action of (Stuart), 373

Preocious development, in a child (Huggins),
126

Pregnancy: extra-uterine (Stadthagen), 26;
(Albu), 26; (Townsend), 271; (Lucker), 461;
influence of heart disease on (Duroziez), 27;
milk-diet in albuminuria of (Tarnier), 124;
prolonged (Wells), 126; telluric cardiac
neuralgia during (Burdell), 270; ovariectomy
during (Baum), 271; seat of murmur in
(Depaul and others), 375, 420

Pregnant woman: effusion of blood into labia
of (Ingham), 414; obliteration of os uteri in a
(Chambaud), 553

Presentation: of four hands (Stiebeling), 171;
face, treatment of (Penrose), 270

Prizes: Howard, 46; on signs of death, 189;
Ribert, 383; Boylston medical, 480; of
Medical and Surgical Society of Bordeaux,
527; of Medical Society of Toulouse,
527

Prolapsus ani: liquor bismuthi in (Cleland),
117

Prostate: fibro-muscular tumour of (Bundy),
550

Pruritus: of vulva, treated by nitrate of
alumina (Gill), 80; by chloral (Gellé), 170

Pseudarthrosis: treatment of (Becker), 547

Psoriasis: origin of (Bulkeley), 508

Psychiatry: object and aims of (Hitzig), rev.,
567

Psychology: aims and objects of (Hitzig), 170

Puerperal fever. See Fever, puerperal.

Pulmonary docimasia, 472

Pulse: carotid (Mendel), 269; slow, in jaundice
(Legge), 361; extreme slowness of, 452

Pupil: action of certain substances on (Mosso),
343

Purpura (Rohlf), 208; hæmorrhagia, in infancy
(Appenrodt), 545

Purulent matter: migration of (Buck), 316

Putrefying tissues: changes in (Tamassia),
448

Pyogenic agent (Chauveau), 1

QUINBY, Dr. F., 27; Quinke, Dr.
216

Quarantine (Woodworth), 510

Quinine: hypodermic injection of (Rouxau),
21; sulphate of in pain (Verneuil), 120;
treatment of sunstroke by subcutaneous use
of (Hall), 224; therapeutic action of hydro-
bromate of (Gubler), 266; (Raymond, Soulez,
and Choffé), 487; eruptions produced by
(Dumas), 459; antipyretic use of (Nickles),
459; cinchonidia as a substitute for, 460;
physiological action of (Jerusalimsky), 499

Rabies. See Hydrophobia

Radius, and ulna, dislocated outwards
(Andrews), 165; congenital absence of (Hodge),
208

Rattlesnake: treatment of bite of (Sacc), 183

Reaction-time, 336

Reflex action of tendons (Erb and others), 8

Refraction: of eye, determination of by oph-
thalmoscope (Loring), 175

Regeneration: of limbs (Philippeaux), 328

Reichenhall: curative resources of (Von Liebig),
267

Religion and hygiene, 479

Ressection: of rib in empyema (Peitavy), 359

Respiration: influence of carbonic acid on
(Raoult), 328

Respirator veil, 571

Retina: curability of detachment of (Gale-
zowski), 129; (Grand), 464; structure of
(Ewart and Thin), 489

Revaccination: during an epidemic of small-
pox (Davis), 366

Rheumatism: in connection with injuries
(Verneuil) 93; acute, Faradic current in
(Abramowski), 167; treatment by packing
with carbolic acid, 169; salicylic acid and
salicin in (Stricker and others), 241; articu-
lar pathogenesis of (Bencke), 305; acute,
treated by cyanide of zinc (Deschamps), 459;
in calculous patients after operation (Courtay),
473

Rhinoscopy: new method of (Voltoini), 558

Ribs: resection of in empyema (Peitavy), 359;
fracture of cartilages of (Bennett), 364; ab-
normalities of (Shepherd), 366

Rickets: Cause and Treatment of (Moore), rev.,
478; marine treatment of (Challe), 501

Roman method of interment, 288

CHAUVEAU ON THE PYOGENIC AGENT.*

During the past year M. Chauveau has continued his interesting researches as to the mode of action of the infective product of virulent inflammations, in a series of experiments which differ from the preceding ones chiefly in this respect, that the infective liquid was introduced into the arterial blood-stream, not into that of a vein.

Twenty experiments were made, the animals used being horses or asses. The infective liquid was obtained from subcutaneous suppurations produced by the insertion of setons. In each case the activity of the liquid was tested by introducing eight drops of it diluted with twice as much water under the skin of another (test) animal. In fourteen of the twenty cases it produced either a transitory swelling or an abscess, but in the remaining six a diffuse gangrenous suppuration, which in four instances was fatal. It was found that there was throughout the series a complete correspondence between the intensity of the transmitted inflammation and that of the primary inflammation from which the infecting liquid was obtained.

Mode of Injection into the Carotid Artery.—The liquid having been diluted with twice or thrice its volume of water, was strained through a filter consisting of numerous layers of *batiste* for the purpose of freeing it from fibrin-flakes and clumps of corpuscles. It was introduced in doses, corresponding from five to twenty drops of pus, by means of a very fine-pointed steel cannula. The greatest care was taken that the external surface of the point of the instrument should be absolutely clean, and that it should remain in the artery after the completion of the injection a sufficient time to free it from adhering pus, it having been previously found that, if this precaution were neglected, local effects were very apt to follow of such a nature as to endanger rupture of the artery.

In all the cases immediate symptoms were produced by the injection. Rigors often supervened even before the withdrawal of the cannula. These were soon followed by sweating and increase of temperature. In fourteen of the cases (the very cases in which the slighter effects were produced by subcutaneous injection in the test animals) these symptoms subsided within twenty-four hours. In the remaining six the subject of experiment became depressed, and then comatose. Soon the muscles of the side opposite to that on which the injection was practised became rigid. Then followed clonic convulsions, which came on in paroxysms of gradually increasing severity, between which the animal was helpless, the previously affected muscles being either rigid or relaxed and paralysed. Death occurred

usually during a paroxysm. In almost all the animals there was general inflammation of the eyeball, indicated by œdema (preceded by temporary injection) of the conjunctiva and opacity of the cornea; after death the anterior chamber was found to contain purulent liquid and purulent exudation-membranes.

The most important *post mortem* appearances were those found in the brain and its membranes. The pia mater was intensely injected, and, at the base and particularly in the Sylvian fissures, beset with purulent exudation-membranes. The cavity of the ventricles also contained purulent liquid and false membranes. The substance of the hemispheres showed everywhere minute foci of suppuration, mostly disseminated, but sometimes confluent. Along with these there were numerous hæmorrhages. Similar appearances presented themselves, but less frequently, in the cerebellum, medulla, and crura cerebri. In no instance could any sign be observed of artificial plugging, all the lesions present being those of acute encephalitis and meningitis. In one case there were infective foci of inflammation in the lungs, but in general the lesions were confined to the area of distribution of the artery into which the infecting agent was introduced.

The results of the investigations are important, first, as showing that, although the liquid employed was in all cases putrescent, it exhibited phlogenic properties only in those in which it was derived from a focus of intense inflammation, whence M. Chauveau concludes that its virulence was certainly not that of mere septicity; and secondly, as affording a better example than any hitherto published of the mode in which the infective product of inflammation acts on the brain when the utmost precautions are used to avoid embolism.

J. BURDON SANDERSON, M.D.

ROEHRIG ON THE INDICATIONS FOR THE USE OF BRINE-SPRINGS CONTAINING IODINE AND BROMINE IN GYNÆCOLOGY, ON PHYSIOLOGICAL GROUNDS AND FROM PRACTICAL EXPERIENCE.*

The indiscriminate recommendation of springs of all kinds for the treatment of complaints of females makes it almost a duty on the part of those who practise at springs of established reputation, in such cases to explain the theory of their operation and their practical employment.

The curative effects of thermal waters depend on their stimulating effect on the nerves of sensation. This results from the fact that the salts of warm waters, when kept for some time in contact with the skin, effect a certain amount of chemical solution of the cells of the epidermis and thus stimulate the skin. The stimulation of the peripheral terminations of the nerves communicates itself to the central portions of the nervous system, the brain and spinal column, and especially to the medulla oblongata, whence by reflex action the most important vital processes are influenced. A warm brine-bath causes a diffused redness of the skin, which takes some hours to return to its natural degree of injection. It is easy to understand how this artificial expansion of the capillaries of the skin must tend to relieve the more distant organs, which may be in a state of congestion; and how the continued use of this mode of

* *Gazette Hebdomadaire*, no. 37, 1875.

* Abridged from the *Berliner Klinische Wochenschrift*, November 15 et seq.

derivation must operate. Further, the powerful action of brine-baths in promoting the transmutation of tissue, increased oxidation, increased secretion of urea, along with diminution of phosphates of soda, and especially of phosphates of lime—all which are well ascertained facts—gives distinct indication for their employment in diseases of women. Not only in chronic affections do the baths do good by stimulating languid constitutions to more rapid transmutation of tissue, but by producing increased oxidation they help materially towards the absorption of old exudations.

But we are especially concerned with the reflex action of brine-baths on the urino-genitary system. It is universally admitted that brine-baths increase the secretion of urine. Of still greater importance to us is the specific stimulation of the uterus by these baths. It has been shown by experiments on animals that chemical stimulation of its surface, or the application to it of electricity, of heat, or of ice-bags, causes active contraction of the uterus. This corresponds with the high practical utility in atonic conditions of the uterus of the use or application to the skin of mustard, of iodine, and stimulating fomentations with strong mother-lye. All this makes it easy to see how the daily stimulation of the skin by the use of brine-baths may react powerfully on the uterus. I cannot enter into detail as to how the operation of salt-baths is supported by the internal use of waters containing iodine and bromine. It is well known that salt waters, when drunk, increase oxidation and secretion of urea, and produce diuresis; and there is little doubt that the quantity of iodides and bromides present in salt-waters helps materially to promote the absorption of exudations, and never produces in the system the disagreeable effects which often follow heroic doses of them.

Admitting all the progress that has been made of late years in the study of the diseases of women, yet I think it must be granted that too much attention has been paid to the use of local measures in their treatment, and too little to constitutional ones. Thus the majority of medical men who have employed for years, and with little result, every variety of local remedies in the treatment of uterine and vaginal catarrh, would have done well to have remembered that it is often an accompaniment of heart and of lung affections, and still oftener of a chlorotic or scrofulous state of system. In fact, all scrofulous patients having a feeble heart with an atonic condition of the blood-vessels, have a tendency to hyperæmia of all the mucous surfaces, and especially those of the uterus. Catarrhs of the mucous lining of the uterine organs, as of other organs, often disappear very rapidly, as soon as the scrofulous cachexia is improved by the judicious use of brine-baths and of preparations of iron, and without any local measures. I therefore cannot too strongly insist that such baths are applicable to almost all cases of uterine catarrh, even though the signs of constitutional disorder may be slight. The effect on the nutrition of the system of its baths has given Kreuznach its world-wide reputation in chronic leucorrhœa, which is so widely spread throughout the low parts of Belgium, of Holland, of the Baltic provinces, and in England. Little more local treatment is usually required than the injection of a mineral water into the vagina, more for the removal of the secretions than for any more special purpose; but it is more efficacious than plain water. Only the patients must be instructed to use the injections

very gently, and not of too low a temperature. The specula to be introduced while bathing, to admit the application of the water to the os uteri, ought also to be selected more carefully than is usually the case, as much harm often follows the employment of too large instruments. Simple washings and cleansing sitz-baths are aids to the use of the injections. The local measures just mentioned are far less effective in chronic uterine catarrh than in chronic hypersecretion of the vagina, because the injections scarcely reach far enough; and the former may be often cured without the use of the local applications, which are wearing out the life of the patient.

It must finally be observed that it is often difficult to say whether the feeble condition of the patient has been induced by the local catarrh, or whether the catarrh is the result of a feeble state of constitution. But, after all, it is not a question of very great importance in ordering the brine-baths, because in any case the main indication is to raise the strength and relieve the poverty of blood of the patient.

The etiology of chronic metritis agrees pretty much with that of chronic endometritis. The same causes produce sometimes inflammatory irritation of the whole substance of the uterus, at other times an inflamed state of its mucous surface, or perhaps the two combined. Parenchymatous metritis, too, seldom springs up independently; it is usually attributable to some disturbance of the circulating fluid, to a scrofulous diacresy, or to a torpid constitution. The first indication is, therefore, to treat the general condition—and this is best done by a strengthening diet, and by brine-baths. Notwithstanding Scanzoni's dictum that a permanent cure of metritis chronica is to be counted an impossibility, yet I am convinced that it is frequently favourably modified by the Kreuznach baths. The baths in one or more seasons in any case moderate the sufferings, and very often cause a gradual improvement, and diminish the chance of relapses. The amelioration takes place chiefly in the older cases, in which the symptoms of local congestion have begun to abate. Powerful stimulation of the renewal of tissue, such as is produced by salt-baths, is the most rational way of acting against the diacresy which lies at the bottom of the affection. Local treatment is comparatively unimportant. Only we must not forget that the amount of stimulation produced by the baths must be carefully proportioned to the degree of irritability of the patient; that the strength, the age, and peculiarities of constitution of the patient must be taken into account. I believe that one of the causes of the success of Kreuznach treatment is that it is the practice there, first to accustom the patient to the use of the milder baths, and, when the skin no longer reacts under their influence, to proceed to the stronger mother-lye waters. But by the use of brine-baths we not only alter the assimilation and nutrition; we can also, by making the waste of the body exceed its assimilation, act powerfully on various plastic exudations which are outside the ordinary circulation, but which may be brought within its limit and be absorbed, owing to the increased oxidation which has been set up. And practically I am able to refer to a whole series of cases in which there can be no doubt that there has been complete absorption of enlargements of the uterus. Of course, it is only while there is a certain amount of active congestion that such results are possible. They cannot be looked for in later stages, when there is retraction of the cellular tissues into a firm fibrous mass, with

occlusion of the vessels. Although the internal use of the Kreuznach springs is frequently combined with the employment of the brine-baths, it must be admitted that the use of other purgative mineral waters is in many cases more efficacious than that of the Kreuznach Elisen well. But these aperient waters are only of use as long as the hyperæmia of the parenchyma of the uterus is still present. We have to add to the ordinary full and sitz-baths, poultices, or moist applications of the mother-lye; which, if kept on during the night, increase the temporary stimulation of the skin to a real eczema, derive from the internal congestion, and diminish the local pain very materially. The general effect of this action on the skin, and secondarily on the muscular tissue of the uterus, may be compared to the effect of sucking the breast in producing contraction of the womb.

We are apt to look with too little hope at completed processes of exudation. As soon as an exudation is cut off from the stream of the circulation, we consider its absorption a hopeless matter. But I believe that an artificially produced congestion, bordering almost on inflammation, and serous effusion, is the best means of resolving the indurated tissues. The difficulty is to keep the congestion within bounds, and not let it run into actual inflammation. On the principles of this theory I account for the admirable effects I have witnessed from the persistent use of continued douches of very warm water, given in a strong jet internally.

I have made very extensive use of injections of this sort, and have on several occasions been gratified in finding that I had produced not only softening, but partial absorption, of hard swellings. I have always first used injections of the water at its natural temperature, and have only very gradually increased it up to 103°. I have found that the addition of the mother-lye to the injections has answered excellently. In cases where the cervix is indolent, I have found the powerful action of the Meyer clyso-pump far more effective than that of the ordinary irrigator. But the occurrence of more unfortunate results shows the greatest necessity for precaution in the use of such procedures, which should never be left to the patient alone. In comparatively fresh cases of exudation, the use of moderately warm injections with Scanzoni's irrigator will be sufficient. On the whole, I believe the bath-speculum to be much more frequently employed than is at all necessary, and, indeed, to be often injurious. Now and then it may be necessary to add at bedtime a sitz-bath to the ordinary full bath; but the position in it is often inconvenient in uterine complaints, and, indeed, may cause slight displacements of the uterus.

What has been already said applies equally well to parametritis and to perimetritis. It is a real pleasure to observe how the methodical use of the baths and of moist warm poultices of mother-lye provokes the complete absorption of old perimetritic thickenings, of ligamentous adhesions between the peritoneum and the uterus, and even of hard tumours of the cellular tissue of the pelvis.

What has been already said prepares us to see how brine-baths may be of service in certain uterine displacements, especially where flexions are the result of relaxation of the uterine textures, which has been produced by general weakness of constitution and by torpid assimilative powers, often, having a foundation in scrofula. In such cases the waters of Kreuz-

nach not only exert their general influence in improving the nutrition of the system, but by their action on the skin exercise a specific influence on the innervation of the uterus, exciting it to contraction. Both in theory and in practice we have many proofs of this. It is a matter of daily experience, that strong poultices of the mother-lye occasion pains in the lower part of the abdomen, which are certainly referable to uterine contraction; and a further confirmation is found in the frequency of abortion in those who are so ill-advised as to use the Kreuznach baths during pregnancy; and another proof is to be found in the beneficial effects of these waters in menorrhagia.

If we consider the various causes of uterine hæmorrhage, we find that they may be referred either to external causes, which produce congestion of the uterus, or to conditions of the nervous system dependent on disturbance of the general system, or of particular organs. In most of these cases the Kreuznach waters are very efficacious; and we need not wonder at this, when we observe the redness of the skin, the immense derivation to the surface, and consequent alteration of circulation, which is produced by the stronger baths. As compared with this powerful influence, the ordinary local measures of stimulation, as the application of blisters, of dry cupping, or of mustard poultices, are matters of but small importance.

When menorrhagia depends on a general atonic condition, the action of brine-baths in restoring tone to the muscular system has a certain analogy with that of ergot; only, as it is less immediate, so also is it more permanent. The brine-baths are indicated whenever there is an anæmic and scrofulous condition, and when a case is one that will profit by fresh air and good nutrition. I would not, however, be supposed to say that menorrhagia occurs only in debilitated women. On the contrary, debilitated females are perhaps more likely to suffer from amenorrhœa. We shall only say about the treatment of this last condition, that from what has been already said about the general tonic influence of baths, it can be easily seen how they may prove excellent emmenagogues. Although dysmenorrhœa may sometimes be dependent on general conditions, yet it is more often so on local ones requiring special treatment. Warm baths and mother-lye poultices, therefore, are of comparatively little value in the treatment of this affection.

It is thus chiefly in cases of irregular menstruation, depending on constitutional causes, that the waters of Kreuznach are efficacious. Where there is the complication of granular erosions, of fungoid granulations, or of polypus, all of which require local treatment, they are of no avail; but they often prove of much value in uterine hæmorrhages occasioned by the presence of fibroid tumours in the cavity or in the walls of the uterus. I do not allude to temporary palliative action on the accompanying hæmorrhages only during treatment at Kreuznach, but to improvement that has lasted for months. Indeed, every year cases are occurring in my practice, where such has been the influence of the treatment on the uterine circulation, that all hæmorrhages, and even the catamenia, have been absent for more than a year. This is a fact which will astonish many practitioners. The most probable explanation of this seems to be, that the baths have induced a firm contraction of the muscular elements of the uterine structure, and possibly of the fibroid tumours

themselves, which may contract at the same time on their fluid and vascular contents. But, apart from all theory, it is a positive fact that the violent menorrhagias connected with fibroid are generally greatly relieved at Kreuznach; and, indeed, this applies to menorrhagia generally, provided the baths are not used of too high a temperature.

It is matter of dispute whether, as some think, fibroid tumours may be dispelled by treatment, or whether, as most physicians think, there are only a few rare cases in which small tumours disappear after labours. Without giving in my adherence to either side, I think I can give some hints which will help to make the use of the Kreuznach waters more precise in such cases. I have never as yet had the good fortune of Dr. Prieger, in seeing any case of fibroid tumour totally absorbed; but I can say in all honesty that frequently, after two or three years' use of the waters, a cessation of its increase has been observed, that in a few cases every year a diminution of the tumour to one-half of its original size occurs, and that other cases generally improve as regards the accessories of such tumours, especially the hæmorrhages. Among ninety-six patients (of whom, by the way, only six were unmarried) there was in twenty-three cases a diminution of size of the tumour by at least one-fourth of its bulk; in forty-eight cases the size of the tumour already attained was not increased; while in the remaining twenty-five cases no influence on the size of the tumour was observed. The most favourable results were in cases where the bath treatment had produced a cessation of the menses from six to thirteen months, and when periodical congestion was thus avoided. Besides baths strong enough to irritate the skin powerfully, I ordered baths of the mother-lye of an hour's duration, and poultices of it to be kept on all night; and these were to be continued for some months at home if the weather be favourable. I soon gave up injecting into the vagina and the use of the speculum, as I generally found them followed by bad effects.

Considering that the curative action of the Kreuznach waters lies chiefly in their stimulation of the skin, I have more and more given up the internal use of the Elisen Spring. I greatly prefer the Marienbad or Kissingen water, because the Elisen Spring is in small doses rather constipating, and, if given in large enough doses to be aperient, is apt to produce catarrh of the bowels. The regular and free action of the bowels always relieved the patients. As the effect of the subcutaneous injection of ergot has been said by Hildebrandt to be the diminution of the tumour by the increased action of the muscular fibres, I thought it right to use it as an adjunct to bath treatment, but I met with no satisfactory results. In fine, if we cannot always very directly influence fibroid tumours, still, as we know that their growth usually comes to an end at the climacteric period, it is of much importance to know that we have in these waters a means of checking the hæmorrhages and of supporting the health of the patient.

The same treatment is of great value in chronic oophoritis, while it entirely fails in ovarian dropsy, which has, of late years, most properly formed only a subject for surgical treatment; and I am strongly of opinion that those who cannot make up their minds to undergo an operation, live longest, who have least to say to medical treatment of any kind. But, although there is no chance of curing such cases at Kreuznach, yet hundreds of them are sent thither every year; and something may be done to improve

their health by the use of the baths, of nourishing diet, and of the lighter chalybeates. I may also mention that a certain amount of benefit is gained in this disease, as in the other congestive ones of which we have been treating, by the patients usually being removed from sexual intercourse while undergoing the bath treatment, which undoubtedly has a very unfavourable influence in all uterine affections.

In conclusion, I may add that I have obtained very satisfactory results in chronic hypertrophy of the mammary glands. I have never effected any absolute cures, but I have also never failed to do some good in such cases. In 20 per cent. of cases of lobular fibroma there has been a palpable diminution of size, and in the other cases the swelling has ceased to make any progress. I have used baths and the Elisen Spring; and as for local measures, after trying every variety of them, I have latterly confined myself to compresses of the mother-lye kept on during the whole night.

J. MACPHERSON, M.D.

BUCQUOY ON PLEURISY WITH GANGRENE OF THE LUNGS.

Nos. 84, 86, 91, 93, and 95 of *L'Union Médicale* for 1875 (July 17, August 3, 7, and 12) contain a paper of great interest, by Dr. Bucquoy, of the Hôpital Cochin, on the association of pleurisy with gangrene of the lungs, and on the question as to the occurrence of a form of pleurisy which is gangrenous from the commencement (primary gangrenous pleurisy). This memoir was read to the Medical Society of the Hospitals on July 9 last, and was suggested by the report of a case of sudden death during paracentesis thoracis in a case of M. Ernest Besnier's, where there was gangrenous pleurisy. As M. Bucquoy's paper occupies nearly a score of pages, we must be contented with an abstract of the cases related, and of the more important points raised in their discussion. Very few such cases are to be found in medical literature. The three now given are, therefore, all the more interesting from their rarity.

The first case is that of a dealer in hair, aged forty-three, admitted November 27 into the Hôpital Cochin. He had had no previous illness, was of good constitution, strong for his age; only, like most who follow this trade, he had been a free drinker. Ten days before his admission he had been wet through, late at night; he was much chilled, and it was some time before he could become warm again. Next day he was wet again, and felt uncomfortable. He returned to Paris from Etampes, and was at once attacked with repeated rigors, cough, and spitting. Very soon violent pain under the left nipple, and increased fever, compelled him to take to his bed. From this day forward he declared that his breath was stinking, and that his sputa 'poisoned him.' On admission eight days afterwards, there was still acute pain in the side, and jerking and painful respiration. The cough was accompanied with a scanty, dirty-grey expectoration, the fetid smell of which was quite characteristic. Pulse 100, temperature 101.2°. There was anorexia; the bowels were regular; the tongue was covered with a whitish coat. There was absolute dulness on percussion in the lower third of the right chest, front and back; absence of tactile vocal fremitus, and vesicular breathing. Some sibilant râles were heard in the left lung. The treat-

ment was dry cupping, and a mixture of carbolic acid; afterwards a saline. There was no change, except more expectoration. More violent cough, and inability to lie down, even at night, were the only changes in the next few days. On November 30, above the dull portion, near the spine of the scapula, bronchial breathing was heard pretty widely, and in one spot cavernous respiration, with moist râles, which, on coughing, became absolutely gurgling in character. From time to time there was distant amphoric breathing. Despite the severity of the local symptoms, the temperature became lower, fluctuating between 101° and 98° 96°. His countenance changed; his general condition grew worse. Tincture of eucalyptus, given in half-drachm doses, instead of the carbolic-acid mixture, seemed to have the effect of quieting the cough and diminishing the fetid odour of the breath and of the sputa; and during some days the patient remained in nearly the same condition, without rise of temperature or pulse (the latter remaining between 80 and 100, the former never exceeding 102°). On December 8, restless but not furious delirium supervened. He sometimes tried to get into the other patients' beds, but generally remained seated, uttering incoherent words and picking at the bed-clothes, etc. The local changes were chiefly dependent on the fulness or the reverse of a cavity. The sputa were less abundant and less fetid; but the cough always revived the gangrenous odour. After a restless night he died on December 10. At the necropsy, when the chest was opened, there was a mixed odour of gangrene and eucalyptus. There was purulent pleurisy of the antero-lateral portions corresponding to the base of the right lung. The pleurisy was completely encysted, and the pouch, which contained 1½ litres (3½ pints) of pus, was divided into two cavities, an anterior and a lateral (axillary) one, separated by a partition containing an orifice admitting two fingers. The partition was formed partly of thickened pleura, and partly of a tongue of indurated and condensed lung. Just above the collection of pus there was a vast cavern scooped out of the middle lobe of the lung, and occupying nearly the whole of this lobe. The outer wall was formed entirely of thickened pleura, the inner and upper one was formed by pulmonary tissue. The walls were lined with greyish broken-down material, with the characteristic odour of gangrene. Above the cavity there were cicatrices of whitish fibrous tissue, and the lung was condensed and blackish grey (iron grey). The lower lobe of the lung was compressed by the pus, and did not crepitate at all. It contained a small cavity with inoffensive serosity. On the left side were old tough pleural adhesions. There were no tubercles in either lung, nor changes in other organs, except congestion. There was commencing fatty degeneration of the liver. The spleen was very friable, and its capsule much thickened and almost cartilaginous.

In this case the pleurisy set in after a common cold, and it is very remarkable that the sputa were fetid from the first day. On this point there seems no reason to doubt the man's word. At all events, in a day or two's time there could be no reason to doubt the gangrene of the lung. Ought we to call this a case of 'primary' gangrenous pleurisy? Certainly not, for it is clear that the lung was first attacked. In M. E. Besnier's case, on the other hand, there were no indications of the horrible nature of the contents until the tapping. We may therefore admit the possibility of a pleurisy gan-

grenous *ab initio*. But even in his case there was no anatomical proof, and we know that there may be most extensive gangrene of the lung without the breath or sputa giving the characteristic fetid odour. Fournet's second case (*De la Gangrène du Poumon, l'Expérience*, tom. i. p. 324) is very instructive as regards this. A young girl, aged fifteen years, who was only ill fifteen days, had a large gangrenous patch at the base of the left lung, which had perforated this organ. There was pleuritic effusion before the perforation, and it was sufficient to reduce the lung to the size of a fist. The effusion had all the characters of gangrene, and the patch affected communicated with the bronchi. Yet in life there was no odour of gangrene in either breath or sputa, nor were the latter at all modified in consequence. Sometimes the fetor is noticed very late. A young man in Dr. Aran's wards at Saint-Antoine, long ill with tubercles, had, when he died, five pints nearly of horribly fetid sanguineous fluid in the pleura. The pleurisy was therefore thought to be primarily gangrenous, but M. Aran divided the lung, and found in the lower lobe a patch of gangrene of the size of a turkey's egg, communicating by a circuitous route with the pleura on the one hand, and with a large dilated and inflamed bronchus of brownish hue. Two days before death, those near him were struck with the fetor of his breath, and noticed that he had spat blood with the same smell. [*Journal de Médecine et de Chirurgie pratiques*, 2^e série, t. xxvii. p. 301, 1856.] Sometimes the pleurisy exists for a considerable time, and the gangrene of the lung supervenes, as in the case of Professor D—, recorded by M. Millard. Of this character is the next case; and when perforation takes place, the pyopneumothorax is usually rapidly fatal.

Case 2.—A carrier, aged forty-three, had pleurisy of the right side, with moderate effusion. He was admitted into hospital on October 30, 1872, after four days' illness, attributed to cold. His previous health had been excellent. On the fifteenth day (November 11), at his own request, he was discharged to go to Vincennes. The effusion had nearly subsided. The pulse had not much exceeded 80, and the temperature was nearly normal all the time. A few days after reaching Vincennes, he noticed his breath to become fetid, and on the sixth day (November 17) he spat a good deal of blood. In spite of this he left, and resumed work on the 19th. After a few hours he began to cough, and, according to his own account, spat up more than a quart of blood. Appalled at this, he re-entered the hospital, very pale, free from fever, with appetite, but his breath and sputa were horribly offensive. The latter were also greyish and ragged-looking. On the 30th his general health began to suffer. The carbolic-acid mixture was replaced by one of tincture of eucalyptus, with opiates. This relieved the horrible frequency of the cough. On December 6 there was fresh hæmorrhage. Then he became worse and feverish. The cough was less frequent still, the expectoration ceased, the gangrenous odour disappeared, and the physical signs were those of hydro-pneumothorax, which could be nothing less than pyopneumothorax. There was a well-marked succussion-sound. Paracentesis was practised, and as soon as the pleura was reached, a jet of badly formed pus, the odour of which filled the ward, escaped. The pleura was well washed out, and, the opening being free, fragments of ragged rotten lung escaped. In the evening he seemed much better.

Three times in twenty-four hours the pleura was injected with one-third spirit to two-thirds water. After a day or two he had diarrhoea and oedema of the feet and legs, and on the sixth day after the tapping he died. At the necropsy the chest-wall was a dirty white (*blafarde* = *blech-farbe*) where the wound was; the edges were blackened and sodden. The periosteum of the eighth rib was mortified, the rib itself slightly necrosed. In this case there was also an encysted pleurisy with two pouches, communicating by a sort of canal, the width of two fingers. The walls of the cyst were formed of thickened but friable pleura (both layers) with many false membranes—and not much pus—owing to the irrigations. There was a patch of gangrene in the lower lobe of this lung, and forming a cavity, in size about that of a hen's egg. No trace of communication with either pleura or bronchi could be found. The contents were fetid sanious pus, with ragged morsels of rotten lung floating in it. There was much congestion and oedema of the left lung, and in its base two small gangrenous caverns. The other organs presented nothing remarkable. Although no communication with the pleura was found, the sudden onset of the physical signs of hydro-pneumothorax shows that it must have occurred. So do the fragments of lung-tissue in the washings. Notwithstanding this case, there may be multiple centres or several patches of gangrene in one or both lungs without the patient's life being immediately compromised, as is shown by the following.

Case 3.—On April 3, 1872, a single girl, aged twenty-two, a sempstress, who had been ill about a month, though previously healthy, was admitted into the same hospital (Cochin). She declared that even in infancy she had often expectorated, from time to time, thick and fetid pellets of mucus, which even filled her mouth. [Naso-palatine catarrh with cheesy tonsillitis?—*Rep.*] On admission there were slight pyrexia, stabbing pain below the right nipple, anxiety, and cyanosis of lips, etc., the skin covered with perspiration. The pain had existed about a fortnight. The middle third of the right lung was somewhat duller than the rest. There were mucous and subcrepitant râles there; and a few moist râles at both apices and in other parts of the lungs. Percussion was painful under the right nipple. There was much albumen in the urine. Although the temperature never rose much, all her other symptoms were much aggravated, the pulse reached 160, her dyspnoea and cyanosis were greatly intensified, and on the morning of the 7th the death-agony began, which terminated at 2 A.M. next day. At the necropsy there was found diaphragmatic pleurisy. About eighteen ounces of serous fluid were between the lung and the diaphragm. It was encysted by soft and recent false membranes. At the base of the right lung there were numerous little pouches (four or five) beneath the pulmonary pleura, from the size of a nut to that of a pea. Incised, they gave exit to a greyish sanious pus, with little odour. The wall of each was formed of ragged ulcerated lung, in direct contiguity with the pus. The rest of this lobe had numerous nodules of disseminated lobular pneumonia. The left lung was congested, and little crepitant. This pleura had also a considerable effusion. The heart was healthy. The liver was congested and of enormous size, the spleen large and very friable. Lastly, a great part of the mucous membrane of the small intestine, and of Peyer's patches, which were unduly prominent, were greatly congested. The mesenteric

glands, however, were not enlarged. In spite of the albuminuria, the kidneys were perfectly healthy.

The interest of the case is not so much in the limited pleurisy which accompanied the gangrene of the lung, but in the form assumed by the latter. Instead of a large tract with extensive destruction of lung, we have a number of small and scattered excavations like metastatic abscesses. There were, besides, all through the affected lobe, numerous nodules of lobular pneumonia, thus resembling pulmonary infarction, though quite distinct from it. M. Bucquoy refers to a case reported by E. Boudet ('Recherches sur la Gangrène pulmonaire des Enfants,' in the *Archives Générales de Médecine*, 1843) in a child aged five, after measles, had gangrene of the mouth. He distinguishes nodular from circumscribed gangrene of the lungs. Dr. Walshe does the same. Dr. Stokes (*Dublin Quarterly Journal of Medical Science*, 1850) insists specially on one important feature of these cases of pleurisy with gangrene in the lung. He says, 'The pain in the side is always more intense in cases of gangrene of the lung than it is in ordinary pleurisy, and the extent to which the pleura is inflamed does not correspond to the amount of suffering.' In one of M. Bucquoy's cases, a medical pupil took cold, and died in eighteen days of gangrene of the lungs. He suffered intense pain during the first ten days, and all the time the only physical signs were slight dulness in the right infrascapular fossa, corresponding to a central gangrene of the lung. The peculiar fetor of the breath and sputa is seldom present at an early period—sometimes altogether absent. Dr. Stokes thinks it sometimes precedes.

Dr. Bucquoy thinks we may divide our cases of pulmonary gangrene into two great classes—viz., the pneumonic or pleuro-pneumonic form, and the pleuritic form. He attributes considerable value as a diagnostic symptom to the presence of blood in the sputa in considerable quantity. The typhoid nature of the symptoms from the first is also characteristic. He refers to Corbin ['Sur la gangrène superficielle du poulmon,' *Journal hebdomadaire de Médecine*, tom. vii. p. 126, 1830]. Corbin's division into deep and superficial gangrenes is really equivalent to the pneumonic and pleuritic forms. M. Bucquoy does not allow that we have clinical proofs of a primary gangrenous pleurisy; whilst, as regards the pleuritic form of pulmonary gangrene, he does not admit the causes usually assigned for its production. For besides local causes, such as inflammation, apoplexy of the lungs, infarctions, foreign bodies, and the like, many general debilitating causes have been specially mentioned; such as privations, disappointments, previous illnesses, and especially mental alienation (Guislain); alcoholism (Copland, W. Stokes); diabetes (Marchal de Calvi), etc. But in the acute form, none of these may be met with in the patient, as in the cases detailed. Some of them were attacked in the prime of life, and had robust constitutions. One cause is, however, common to a great many of them—that cause is extreme and prolonged cold. It was so in many of Dr. Stokes's cases. So it was in Professor D.'s case, exposed during his lectures to a strong draught of cold air, which led to an illness which long threatened to be fatal. It is not probable that the cold produces gangrene of the lung exactly as it does gangrene of external parts, as Grisolle supposes, on the strength of two cases by Shrimpton and Dubasc-Montfaucon (Inaugural thesis, 1847). It has sometimes seemed to be traumatic (case by Jackson in the *Archives Générales de Médecine*,

1853, and a case reported by M. Hayem last year). M. Bucquoy admits the difficulties of diagnosis ; and concludes with a warm recommendation of the tincture of eucalyptus in half-drachm doses, repeated frequently, as often tending to cure, and always tending to relieve the horrible fetor of the breath and sputa.

W. BATHURST WOODMAN.

GOLTZ ON VASO-DILATOR NERVES.

Goltz, with the co-operation of Drs. Frensenberg and Gergens (*Pflüger's Archiv*, Band xi. p. 52), has continued and extended his researches upon this subject (LONDON MEDICAL RECORD, December 16, 1874). Goltz explains the dilatation which occurs after section of nerves, not by a paralysis of vaso-constrictor nerves, but rather as the result of the stimulation of vaso-dilator fibres. In accordance with the results of Putzeys and Tarchanoff (*ibid.*), the author corrects a mistake in his previous observations, and agrees with these authors, that, in many cases, the effect of electrical and chemical stimulation of the sciatic nerve is at first to cause a contraction of the vessels of the foot, of short duration, before the very pronounced dilatation occurs. Goltz, however, does not accept the explanation of Putzeys and Tarchanoff. The method of experimenting is the following. The spinal cord of a strong young dog is divided in the lumbar region. After the wound has healed, both sciatic nerves are dissected out and divided, and a period of time is allowed to elapse till the elevated temperature of the hind limbs has begun to decrease somewhat. The idea of the author was, that if simple section of the sciatic nerve act as a stimulus, this stimulus may be perhaps greatly increased, by making methodically a large number of sections of the nerve. The result showed that the foot whose nerve was only once divided, was generally ten degrees cooler than the foot whose nerve was cut away or divided in repeated small discs. Powerful dogs, full-blooded and with good appetites, are required for these experiments. According to the author's hypothesis, repeated pinching or section of the nerve produces a stimulation of the vaso-dilator nerves. The vessels relax at the periphery, similar to the stoppage of the heart's action when the vagus is stimulated. When the vessels have relaxed, *i.e.* when their tonus disappears more and more, there is not necessarily a pronounced dilatation of the lumen of the vessels. This will only become clearly pronounced when there is sufficient blood to fill the relaxed vessels, corresponding to their diminished elasticity. The pronounced vascular dilatation, and the increase of temperature, will accordingly only occur when the general arterial blood-pressure is high and remains high.

What the author means by the term 'stimulation of vaso-dilator nerve-fibres,' is, that simple or repeated section of the nerves produces a peculiar change in the condition in the nerves, in consequence of which a something is propagated in the nerve, which causes a vascular dilatation in that area in which the peripheral expansion of the nerve takes place.

Hammering the nerves by means of Heidenhain's tetanometer, also produces a similar dilatation of the vessels of the feet, just like methodical pinching of the nerve.

A chemical stimulus, in the form of concentrated sulphuric acid, applied to the sciatic nerve of a

guinea-pig prepared as above, gave the same result, though the author could not be certain whether the foot of the stimulated leg became paler at the beginning of the stimulation than before it.

A very curious phenomenon was observed when the sciatic nerve of a kitten was stimulated by induced electricity, *viz.*, the foot began to sweat. The author, therefore, concludes that, in the sciatic nerve of the cat, fibres are present which supply the sweat-glands. Only in two cases, however, was this effect observed in dogs, who, as is well known, possess sweat glands in the pads of the feet [and also in the skin over the surface of the body generally.—*Rep.*] In many experiments a cooling, *i.e.*, constriction of the vessels of one leg, occurred, when in the other leg vascular dilatation was artificially produced. It is very probable, the author thinks, that the vascular constriction is not referable to an increased tonus, but is to be explained on purely physical grounds, by a sudden diminution of the resistance in the vessels of the other leg.

After simple or repeated section of the sciatic nerve in dogs, the author never observed that the dilatation of the vessels was preceded by contraction, although he remarks that if the contraction were sufficiently short it might elude observation. This contraction of the vessels after section of the spinal cord is well established for the frog.

From the rapidity with which the vascular tonus is re-established after section of the nerves, the author concludes that the tonus must be kept up by arrangements which lie beyond the great nerve-centres, probably in the vascular wall. The tonus was soon re-established in the vessels of the leg of the dog after section of both the sciatic and crural nerves. The author shows in another way that the tonus of the paralysed limb does not depend on the great nerve-centres.

Section of the spinal cord is capable of producing vascular dilatation, not only in the hinder but also in the anterior part of the body. The whole brachial plexus in a dog, on one side, was divided, and when the temperature of both fore-limbs had become nearly alike, generally in from seven to fourteen days, the spinal cord was divided between the thoracic and lumbar portions. There then occurred a considerable difference in the temperature of the two fore-feet, that of the paralysed side having become notably diminished. The temperature of the sound side rose or remained the same. From this it appears that injury to the spinal cord acts similarly both on the fore and hind parts of the body. According to the author, injury to the spinal cord cannot exercise any influence on the tonus of the vessels through nervous channels, the tonus being sustained by the hypothetical end-arrangements in the paralysed part, these being no longer influenced by nervous excitations proceeding from the great centres, still they may not be completely independent of the body. Every change in the blood-pressure in the aorta may alter the diameter of the vessels in the paralysed part ; and it seems to the author very probable that the tonus of the vessels of the paralysed side is increased by the sudden diminution of the blood-pressure acting locally on the isolated end-organs. In experiments where double section of the spinal cord was performed at long intervals, *e.g.*, first in the lumbar region, and then in the fore part of the thoracic region, it was found that the hind feet, immediately after the second section, became greatly cooled, while the fore feet became warmer. This

shows that, in an animal with divided spinal cord, the tonus of the vessels of the hind feet are governed from foci other than those of the fore feet. The peculiar reflex actions of the hind part of the body were influenced by the second section. The author thinks that this experiment supports the view that the cause of 'shock' is to be sought in 'inhibitory processes,' which are propagated in nervous channels.

The most pronounced vascular dilatation can be produced by placing the paralysed limb in a freezing mixture. When the foot is taken out of the mixture, its temperature is little short of that of the blood itself.

Variations in the temperature of the air of the room, however, produce extreme changes in the diameter of the vessels of the paralysed limbs. The tonus in the paralysed limb varies with a change in certain internal conditions—probably blood-pressure, the quantity of blood, temperature or change in the composition of the blood may influence it, but these the author has not sufficiently studied.

With regard to the end-arrangements in the sound limb, the author imagines that they are equivalent to the nervous arrangements upon which the activity of the excised heart depends; and, just as Volkmann maintained that the ganglionic cells are the immediate central organs for the cardiac movements, so are the hypothetical ganglionic cells in the walls of the vessels the immediate centres for the vascular tonus. In sound limbs, the activity of these end-arrangements can be powerfully influenced by the great nerve-centres.

The reasons why the author regards the vascular dilatation as a result due to stimulation, which must be explained by an increased activity of the divided nerve, are: (1) the vascular dilatation disappears tolerably rapidly, because the stimulus becomes exhausted; (2) repeated section of the peripheral end of the nerve increases the dilatation; (3) every other form of mechanical stimulation produces the same result; (4) continued chemical or electrical stimulation of the divided nerve always produces a degree of vascular dilatation which greatly exceeds that which is present before the stimulation.

Goltz is of opinion, that those cases where sometimes section of the sympathetic in the neck is not followed by its usual results, support his hypothesis. He also cites the division of the nervi erigentes, and one on which he lays more weight, viz., Vulpian's experiment of section of the lingual nerve being followed by dilatation of the vessels of the corresponding half of the tongue, and the increase of this dilatation on the peripheral end of the nerve being stimulated; and he also cites the same author's more recent experiment on section of the glossopharyngeal nerve having a similar action on the posterior part of the tongue (LONDON MEDICAL RECORD, November 15, 1875) as supporting his view.

The author concludes that the spinal cord is, undoubtedly, an independent reflex vaso-motor centre. It has, however, not been proved that this centre continually sends tonic excitations to the vaso-constrictor nerves. The dilatation of the vessels observed after injury to the spinal cord, and which is regarded as a consequence of the interrupted activity of this organ, is much more the result of the stimulation of vaso-dilator nerves.

WM. STIRLING, D.Sc., M.D.

ANATOMY AND PHYSIOLOGY.

ERB AND OTHERS ON THE REFLEX ACTIONS OF THE TENDONS.—Several papers have appeared upon this somewhat novel subject lately, including those of W. Erb (*Archiv für Psychiatrie*, Band v. p. 792), C. Westphal (*Ibid.* p. 803), and A. Joffroy (*Gazette Médicale de Paris*, nos. 33 and 35), all of which are reviewed in the *Centralblatt für die Medicinischen Wissenschaften*, no. 54, 1875. Erb noticed these reflex actions of tendons in the healthy subject, but more pronouncedly in many patients suffering from disease of the spinal cord. In the quadriceps, a prompt contraction of the whole muscle, resulting in powerful movement of the leg, is produced by gently touching the region of the ligamentum patellæ, when the knee and hip are slightly bent. The author calls this a 'patellar tendon-reflex,' and shows that it does not proceed from the skin, and can only arrive from the tendon and its direct continuation (no stimulation of the skin, no tapping the surrounding parts, can produce the reflex action), and that it is specially or exclusively the mechanical stimulus which discharges this reflex action. In a patient suffering probably from commencing sclerosis of the lateral columns, the author could produce not only reflex action of the patellar tendon, but reflex contractions could also be produced in a similar way, and in many other musculo-tendinous areas of the body, such as in the tendon of the triceps of the upper arm, and, most peculiar of all, in the tendo Achillis, when suddenly placed upon the stretch by rapidly flexing the foot dorsally. On continuing the pressure, clonic contractions occur; the foot, being flexed by the contraction of the tendo Achillis, is brought back by the continued passive dorsal flexion into the position in which the extension and therewith the stimulus to the contraction of the tendo Achillis occur. These clonic spasms are not caused to cease by sudden plantar flexion of the great toe (Brown-Séquard), when at the same time there is not a powerful flexion of the whole foot. Then the clonic spasms cease. The physiological and the pathological importance of these tendon-reflexes are only indicated by the author.

Westphal, like Erb, also observed the occurrence of the above described phenomena. The phenomena described by Erb as 'patellar tendon-reflex' is called by Westphal 'leg-phenomenon,' the clonic contractions of the foot caused, according to Erb, reflexly by stretching of the tendo Achillis, Westphal calls 'foot-phenomenon.' From a clinical point of view, Westphal noticed the foot-phenomenon in hemiplegics (not in quite healthy persons) at the earliest after the first week since the attack. In the later stages, its occurrence is almost to be regarded as the rule. It also occurs in spinal paraplegics, or in persons weak only in one lower limb from spinal disease, specially in those forms of paraplegia which are accompanied by continued rigidity of the entire muscular structure of the lower extremity. Westphal also regards the assertion of Brown-Séquard, that plantar flexion of the great toe is able to interrupt the clonic spasms, as erroneous, and explains the occurrence of the phenomenon caused by the plantar flexion of the whole foot. The foot-phenomenon is always wanting in the pronounced clinical conditions of tabes dorsalis. The leg-phenomenon generally occurs where the foot-phenomenon occurs; not unfrequently there are exceptions to this rule, only this

is certain that it is absent in all undoubted cases of tabes dorsalis. In grey degeneration of the posterior column, proved by pathological examination, both phenomena are absent, but are to be met with in the most different affections of the brain (embolism, tumour, hæmorrhage), and in the spinal cord in primary myelitis or that caused by disease of the vertebræ, when the grey substance is not too deeply involved, or large parts of the dorsal and lumbar portions of the spinal cord are not completely destroyed. Westphal is inclined to ascribe the *phenomena of the contraction* to a direct mechanical excitation of the corresponding muscles, by sudden stretching or vibration of the tendon, for one cannot explain the phenomena as produced reflexly through sensory muscular nerves, as long as the existence of such nerves is a subject of controversy, and with regard to reflex actions which result from tendons we up to the present know nothing. In the pathological cases the author believes that the continued abnormal condition of contraction of the quadriceps and of the muscles of the calf, which makes them more susceptible of mechanical stimuli, plays a certain part. The author, from his anatomico-pathological observations, is of opinion that a defect in the conduction of the lateral columns stands in causal connection with the phenomena.

According to Joffroy, the above-described phenomena are reflex, and they can be produced by actual muscular extension (which the author regards as of more importance for the occurrence of the phenomena than stimulation of the tendons), as well as by stimuli applied to the skin.

Drs. F. Schultze and P. Fürbringer, stimulated by the above publications, have also experimented upon this subject (*Centralblatt*, no. 54, 1875). The muscles of the thigh and leg of a rabbit were exposed, and tapping of the patellar tendon with a small hammer caused contraction of the right quadriceps and extension of the right foot, weak contractions in the left quadriceps, and irregular tremor of both extremities. After section of the right crural nerve the contraction of the right quadriceps ceased. Section of the left crural nerve was followed by the same result in the left leg. From these and experiments similar in kind with section of the cord at the level of the dorsal vertebræ, the authors arrive at the following conclusions. 1. The phenomena in question are not due to mechanical muscular contractions produced directly through the tendons. 2. They are rather to be ascribed to a reflex mechanism discharged by a mechanical stimulation of the tendons, the reflex path for the lower extremities being placed in the lower sections of the spinal cord. 3. Cutaneous reflex actions as described by Joffroy do not exist.

HERMANN ON ELECTRICAL STIMULATION OF THE CEREBRUM.—L. Hermann (*Pflüger's Archiv*, Band x., p. 77) upon repeating Hitzig's experiments, remarked that, notwithstanding the surface of the brain being exposed for hours together to the air, and also in spite of the surface becoming dry, still the results of the experiment were not affected thereby. The same result was obtained after the destruction (by the repeated application of acetic or nitric acid) of the 'centre,' previously exactly mapped out on the surface. The grey matter of the cerebrum was affected to one-third of its depth by the acid. The experiments were made on middle-sized dogs. The active area or 'centre' was found to be increased by increasing the strength of the current

(induced), though the constant current was also employed.

In all the other experiments a cork-borer of six or seven millimètres (about $\frac{1}{4}$ inch) in diameter was pushed into the brain to a depth of one to one and a half centimètres ($\frac{1}{4}$ to $\frac{1}{2}$ inch); the upper free surface of cylinder of brain-tissue thus produced was formed by the 'cortical centre.' On applying the stimulus (electrical), the results were the same; and even if the electrodes were sunk into the cavity, or placed in its walls, exactly the same results followed. The animals lived four or five weeks afterwards, and were employed for other purposes.

The 'area' was always mapped out by a minimal current. In some cases the 'area' was traversed by a small sulcus, in others not.

Hermann agrees with the other experimenters that electrical stimulation, by placing the electrodes upon certain convolutions, is followed by distinct movements; but he regards the conclusion, that motor centres lie at these spots, as quite unjustifiable. Further, the author observed in a dog, which lived for several weeks after the operation of extirpation of the so-called 'centre' for the right hind foot, similar phenomena, such as have been described by other experimenters (Duret and Carville); but it was distinguished by having perfect anaesthesia of both extremities of the right side, and incomplete anaesthesia of the left hind leg and the left side of the trunk.

GERLACH ON THE RELATION OF SULPH-INDIGOTATE OF SODA TO THE TISSUES OF THE LIVING BODY.—L. Gerlach, of Erlangen (*Centralblatt für die Medicinische Wissenschaften*, no. 48, 1875), adopted the method of saturating the tissues with this substance for days and even weeks together; the former experimenters, Heidenhain, Kupfer, Von Wittich, and Thoma, only injected such a quantity of indigo-carmin as remained in the body for a comparatively short time. The author injected indigo-carmin into the lymph-sac of several frogs, and killed them at intervals of two days, always renewing the injections. The microscopic examination showed that the white blood-corpuscles are capable of taking up indigo-carmin.

1. The first traces of this action appear on the third day after the introduction of the colouring matter. After this time, both the number of cells which contain the pigment and the quantity of pigment in the individual cells increase.

2. The cells of the connective tissue, e.g., of the tendons, take up the colouring matter. This is to be observed from the fourth day.

3. No indigo-pigment is deposited in the bone-cells.

4. The pigment is found in the cartilaginous tissue, e.g., the articular cartilage of the hip-joint, from the fifth day onwards. None is found in the ground-substance or matrix.

5. The nerve-cells never contain the indigo; only in a few cases was it found in the sympathetic ganglion-cells between the cell-contents and the sheath.

6. The blue colouration of the epithelial cement pointed out by Thoma and Küttner is also true for that of the so-called endothelium.

WM. STIRLING, D.Sc., M.D.

TAIT ON THE UMBILICAL CORD.—In the last volume (vol. xxiii. p. 498) of the *Proceedings of*

the *Royal Society* is an abstract of a note on the anatomy of the umbilical cord, by Mr. Lawson Tait, read before the Society on April 28, 1875. This structure is dealt with in the following sections. 1. External Form and Method of Growth. Experiment shows that the vein, and not the arteries as has hitherto been supposed, is the chief factor in the cause of the spiral twist. This twist must depend upon some mechanism at the foetal insertion. An unequal nutrition of the cord caused by the distribution of nutrient capillaries over its venous surface in a proportion of three to two on the arterial surface, would seem to result in a spiral. 2. The Covering of the Cord. The epithelial covering of a cord previously stained with hæmatoxylin, is seen to consist of a single layer of polygonal cells, resting upon a fibrillar matrix. On the surface are stomata, both spurious and true; the latter leading into the vast system of canals of which the proper system of the cord consists. 3. The Substance of the Cord. The canalicular tissue of the cord is divided longitudinally into three columns, the divisions between which are rendered visible by injection of the columns according to Recklinghausen's method. When empty, the canals, by collapse of their walls, have the appearance of fibrous tissue, but look like stellate cells when partly distended. This led to the erroneous description of stellate cells in a fibrous matrix. Oval nuclei are imbedded in the lacunar spaces of the canals. Injected fluid passes more freely in the direction from the fetus to the placenta than in the reverse way. During injection, minute streams of the fluid injected flow from the surface of the cord. These are not due to rents. Transverse and longitudinal sections show that the canals are stellate in every plane. The wandering cells are found in the alveoli between the canals. They are not constant, and are often more numerous in some parts of the cord than in others, but are most abundant near the umbilicus. They exhibit amoeboid movements, after being treated with litmus on a warm stage. No nerve-fibres have been detected in the cord. The canalicular tissue ends in three cones, one for each column of the cord, the apices being just within the dermal ring. The injection will not pass through the tendinous ring, but from the canalicular tissue into the capillaries of the cord. After injection of the capillary plexus running from the dermal ring, a peculiar vascular arrangement will be brought to light, in the centre of the cord, in the firm nucleated tissue forming the omphalic ring. The basis of this system is a sacculated sinus, excavated in the fibrous tissue, and having probably a spinal arrangement, as in one section it appears and disappears as only a screw would. It extends into the true substance of the cord, giving off at intervals branches which break up into capillaries, which latter do not form layers, but enter directly into the canalicular tissue. The sinus seems to originate from the small arteries of the anterior abdominal wall, which enter with the vein. There seems to be a very close analogy between this arrangement and that of the Haversian system in bone. 4. The Vessels of the Cord. Their outer layers have wider limits of contraction than the inner, the latter being thrown into folds resembling those of the contracted oesophagus, or the contraction of the arteries. One reason of this exceptional contractility is, that the fibres of the muscular tissue are arranged in bundles having a double spiral direction. The quality of the

blood traversing the vessels appears to govern this contraction, for the fibres contract as soon as the blood in them becomes arterial by the establishment of respiration, but relax again and pulsate if it becomes venous by a temporary arrest of respiration. This appears to be aided by the absence of an epithelial lining to the arteries. The closure of the vessels is affected immediately by clot, and afterwards by agency of the round migratory cells, which latter also share in the subsequent process of inflammatory ulceration and necrosis of the stump of the cord. 5. The relation of the Cord to the Placenta. Fluid cannot be injected from the substance of the former into the latter, for it is arrested by a firm membrane derived from the chorion, which the vessels of the cord penetrate, and between two layers of which they lie. There is no connection whatever between the nutrient system of the cord and that of the placenta. 6. The Nutrition of the Cord. The arrangement of the capillaries entering it from the fetus is the chief agent in its nutrition; but from what has been observed in cases of extra-uterine gestation, the stomata on the epithelial surface play an important part in its nutrition. From the substances which enter into its composition, we are tempted to conclude that the liquor amnii is a nutrient agent; for, in recent cases of extra-uterine foetation, before the fluid is absorbed, the cord remains plump, but shrivels after its absorption, though still, with the exception of the absence of the wandering cells, retaining its structural character. It is possible that the canalicular nuclei are able to keep the cord in repair, as it were, through the matters absorbed from the liquor amnii, as long as this lasts, very much as ivy continues to live after its connexion with the root has been severed; the analogy, indeed, between the cord and vegetable tissue is a very close one.

RANVIER ON THE MYOSPECTRUM.—In the *Centralblatt für die Medicinischen Wissenschaften*, October 23, 1875, is an abstract of two papers by Professor Ranvier on the spectrum produced by striated muscle, contributed to the *Comptes Rendus* (tome lxxviii. 1874), and the *Archives de Physiologie* (1874) respectively. The source of the spectrum depends upon physical causes similar to those which produce the so-called 'lattice (*Gitter*) spectra,' for the transverse striæ of the muscle have a physical action identical with that produced by delicate cross-bars scratched upon glass with a diamond. In order to have the means of seeing myospectra, one must proceed thus. From a muscle of a freshly killed animal, e.g. a frog or a rabbit, a regular group of primitive fasciculi must be isolated, and teased out upon a glass slide, without, however, the addition of any fluid reagent; care being taken that the primitive bundles are lying parallel. A thin glass cover is then laid over the preparation, and securely cemented with paraffin to guard against evaporation from and consequent drying up of the object. In order to observe the spectrum the room must be darkened, and a single pencil of light only be admitted through a slit in the shutter. The observer then holds the preparation close in front of his eye, having the primitive fasciculi so relatively disposed (*orientist*) that their longitudinal axes lie perpendicularly to the axis of the slit. There are then to be seen on each side of the slit, one, two, or three symmetrically arranged spectra, of which the first is brightest, but of the least extent. In order to avoid the trouble of preparing

fresh objects on every occasion, a preparation can be permanently put up in Canada balsam. The unstriated muscular fibres show no spectrum, nor has M. Ranvier yet succeeded in obtaining any from the muscular tissue of the heart. It is known that the extent of a 'Gitterspectrum' is limited by the number of lines, the spectrum being longer the greater the number of lines in a given space; hence it follows that the spectrum of a muscle is the longer the finer its transverse lineation is. Conversely, from the myospectrum the distance between the transverse striæ can be calculated, the spectrum being compared with that of a lattice of lines of known fineness, or, after that, empirically, by micro-metrical procedure, the corresponding distance of the transverse lines to a row of myospectra has been found out. If the living muscular tissue of a frog be tetanised, while the spectrum is still under observation, the latter will be seen to be extended, but never to disappear. Spectra were observed when a muscle was at rest, as well as in full action, and in intermediate stages of action. This tends to show that the statement of Merkel (*Centralblatt*, 1872, p. 453), that in the contraction of a muscle there is a 'homogeneous intermediate' stage (*Zwischenstadium*), is incorrect. M. Ranvier has even gone so far as to construct a 'myospectroscope.' J. C. GALTON.

BLOCH ON THE HIGHEST TEMPERATURE BEARABLE BY THE HAND.—No. 25 of the *Gazette Hebdomadaire* (June 12, 1875) states that Bloch investigated the highest temperatures which the hand could bear in baths of different substances for two minutes at a time, and the following are the results obtained:—

Substances.	Centigrade.	Fahrenheit.
Quicksilver	48°	118° 40'
Water	49°	120°
Solution of tannin . .	49°	120°
Vinegar	51°	123° 80'
Solution of sodium carbonate }	52°	125° 60'
Alcohol	51°	123° 80'
Milk	52°	125° 60'
Spirits of turpentine .	55°	131°
Glycerine	57°	134° 60'
Oil	60°	140°
Beef-suet	65°	149°

The reason that mercury and solution of tannin at low temperatures seem as hot as other things at higher temperatures, is, according to Bloch, the density of the former, and the rapid imbibition of the skin in the latter.

RANSOME AND PATCHETT ON THE POSITION OF THE HEART'S IMPULSE IN DIFFERENT POSITURES OF THE BODY.—In vol. ix. of the *Journal of Anatomy and Physiology*, Dr. Arthur Ransome publishes a number of observations, based upon chest-rule measurements [taken for him by Mr. W. A. Patchett, resident medical officer of the Manchester Workhouse Infirmary], the object of which is to ascertain the position of the 'apex-beat' of the heart, or, more properly, of the site of the cardiac impulse. The 'chest-rule,' invented by Dr. Ransome, has already been mentioned in our pages. It consists of a rectangular parallelogram, six inches long by three in width, and divided into eighteen squares of exactly one inch length of side, made of the finest spring steel. The statements of authors on the site of the heart's impulse vary greatly from one another. Quain and Sharpey, Sibson, Walshe,

Piorry, and others, are quoted to show this; and the cause is imputed to the difficulty of describing 'in words the extent to which the impulse gravitates downwards or slantwise, or from side to side; this can only be done satisfactorily by means of ordinate measurements, vertically down the central line of the sternum, and horizontally at right angles to this line.' The measurements referred to were taken from fifty-one persons not suffering from any known cardiac disease. The position on the chest-wall where the strongest beat of the heart was to be felt was marked with ink or coloured collodion; first in the recumbent, then in the sitting or standing position; then when lying on the left side; lastly, when on the right side. The latter was often doubtful, and is frequently omitted from the tables. After these points had been marked, 'it was easy to measure their ordinate distance, first along the vertical line down the centre of the sternum (x), and, second, along a line through the point at right angles to the vertical (y).' The measurements are given in detail in the tables, which are arranged according to the length of the sternum. As might be anticipated, the left nipple varies greatly in position. Thus, in those with a sternum of eight inches, the extreme vertical ordinates of this nipple were four and six and a half inches, and the horizontal ordinates varied from three to four and a half inches. 'The relation of the heart's impulse-site to the nipple, when supine, varied from immediately under the nipple to one or one and a half inch within it. Six out of the eight cases in which it was just under or in a line with the nipple, had either chronic bronchitis or phthisis,' and should therefore, probably, be excluded. The difference in the position of the heart's impulse-site is greater in changing position from side to side, than in changing from the lying to the upright position. In twenty of the fifty-one cases its level was the same in the upright and recumbent position. In the rest it varied from a quarter to one inch. In nine cases it was lowered a quarter of an inch; in twelve, half an inch; in three, three-quarters of an inch; and in three, one inch.

The size of the individual seems to make little difference. In 60 per cent. there was a small movement of the impulse to the left as the patient rose to the upright position, and in some instances this occurred even when there was no sinking in the level of the heart. The extent of this sidelong impulse varied from a quarter to one inch along the horizontal ordinate. 'The mean extent of the movement in the whole number of cases was about three and three-quarters inches, the maximum was five and three-quarters inches [? hypertrophy] and the minimum two inches.' [*Extent* probably means area of cardiac impulse.—*Rep.*] Dr. Ransome draws the very just conclusions that variations undoubtedly occur in the site of the heart's impulse, and that, 'in all observations, great care should be taken to place the patient in the same posture at each observation, otherwise most serious errors might easily be made.'

W. BATHURST WOODMAN.

WEGSCHEIDER ON NORMAL DIGESTION IN INFANTS.—In a pamphlet (*Ueber die normale Verdauung bei Säuglingen* (Hirschwald: Berlin). Wegscheider describes investigations conducted in Hoppe-Seyler's laboratory at Strassburg, which consisted in the chemical and microscopical examination of the dejections of healthy infants nourished exclu-

sively at the breast. The following are the results arrived at by the author.

1. The albuminous substances derived from the milk are completely absorbed. [In the text, the presence of traces of peptones is allowed.—*Ref.*]

2. The so-called 'milk-detritus' consists essentially of fat, associated probably with remains of intestinal epithelium. It is not undigested casein.

3. The absorption of fats is by no means so complete as that of albuminous substances. A part leaves the intestine, certainly, as soap; another part as free fatty acids; and, perhaps a third part as unchanged fat.

4. In reference to the bile-constituents, it is shown that, even in the first weeks of extra-uterine life, the conversion of the colouring matter (through reduction in the intestine) takes place; but, in addition to hydro-bilirubin, unchanged colouring matter is always distinctly present; later, however, its conversion appears to be complete. In slight derangements of the intestine, the presence of biliverdin was unmistakably recognised; produced perhaps by the greater acidity of the accompanying fæcal matter.

5. With regard to cholestearin, the proportions correspond completely to those which have been found in adults and in the foetus.

6. Of the intestinal ferments, only the diastatic and the fibrin-digesting ferment of the pancreas were found; the former in small quantity, the latter only in traces. No pepsin could be detected.

The most important of these results is probably that which relates to the constitution of the 'milk-detritus,' i.e. the white specks which commonly appear in the stools of infants, and which have been generally mistaken for undigested casein. The reactions may therefore be acceptable. On examination they were found insoluble in water, in acids, and in alkalies. On the contrary, when treated with ether and alcohol, only a minute portion remained behind. This, on the addition of soda, did not dissolve, but swelled up, and was converted into a clear transparent mass, without definite structure.

RALPH W. LEFTWICH, M.D.

OTT ON THE ACTION OF LYCOCTONIA.—This vegetable principle is found in the *Aconitum lycoctonum*, and an account of some experiments made upon it by Dr. Isaac Ott, of Philadelphia, is given in the *Philadelphia Medical Times* of Oct. 16. He says, with a dose of '005 to '06 gramme subcutaneously in frogs, sensibility remained intact, the spinal cord appeared not directly affected, the motor nerves were paralysed, muscles excitable, pupil contracted, disappearance of respiratory movements, heart beating for a very long time after the absence of every sign of life. In the majority of cases he found the motor nerves completely non-irritable, but in some frogs, without regard to species, and even in the same species, the motor nerves were not completely paralysed. As to its effects upon the circulation, it was found that immediately after its injection into rabbits the pulse waves were considerably greater and steeper. In small doses, like aconitia, its action on the heart causes a delirium cordis, that is, periods when the pulse is greatly slowed whilst the pressure rises and falls in a manner not to be predicted. In larger doses there is reduction of both the pulse and the blood-pressure. The vagi are not paralysed by small doses, while they are so affected by large ones. The following are the conclusions

arrived at. 1. *Lycoctonia* is a weaker toxicant than aconitia. 2. It kills mainly through the respiratory apparatus. 3. It paralyses the motor nerves. 4. It does not affect the sensory nerves, spinal cord, or the striated muscles. 5. It reduces the blood pressure and pulse without any previous rise of the former as produced by aconitia. 6. The decreased pulse-rate and pressure are due to any action on the intercardiac nervous apparatus. 7. The pneumo-gastrics are paralysed only by large doses. 8. The delirium cordis produced by small doses is due to a change in the mechanism of the nervous apparatus of the heart. J. MILNER FOTHERGILL, M.D.

PATHOLOGY.

SATTERTHWAITE ON BACTERIA: THEIR NATURE AND RELATION TO DISEASE.—Dr. Thomas E. Satterthwaite has a paper on the above subject (*New York Medical Record*, Dec. 18 and 25, 1875).

After reviewing the various views of authorities on the nature of bacteria, Dr. Satterthwaite gives details of several experiments performed by himself and Dr. Curtis. The results at which they arrived as to the nature of bacteria and the properties of putrid matter he states as follows. 1. Putrid matter, when introduced into the system, is capable of producing a well-marked train of symptoms, which are extraordinarily like those generally known as sepsis. 2. The poisonous quality does not reside in the absolutely clear liquid, when entirely freed from granules. 3. The poison is sometimes separated by coarse methods of filtration, that is, through common filter paper, though on this point the results were not sufficiently uniform to establish certain conclusions. 4. Continued boiling and evaporation to dryness will

not destroy the poison. 5. Continued boiling and evaporation to dryness, and boiling with absolute alcohol, will not destroy the poison. 6. The dry alcoholic extract, freed of alcohol by evaporation with heat, was poisonous. (The liquid alcoholic extract furnished uncertain results.) So far as this experiment may be relied upon to show the albuminous nature of the poisons it is uncertain, for where the alcoholic precipitate (in which doubtless the albumen would be) produced poisonous results, it still remains uncertain whether the liquid alcoholic extract was poisonous or not. 7. Of putrid matter which, after several filtrations, was boiled down to dryness, then boiled with absolute alcohol, again dried and extracted with water, the filtrate was poisonous. 8. This aqueous extract failed in a number of instances to produce bacteria, under circumstances favourable to the development of bacteria; and hence the granules, which are the bodies most likely to represent the poisonous principles, appear not to be bacteria or their spores.

Dr. Satterthwaite then proceeds to review the arguments brought forward in favour of the germ theory in its application to various affections, and narrates some experiments by Dr. Edward Curtis and himself with regard to the effect of salicylic acid on the poisonous action of putrid substances. They found that salicylic acid in the proportion of 1 to 100 with a little phosphate and soda as a solvent, and carbolic acid of the same strength, have, each of them, the power of preventing the formation of bacteria for a period of two months at least. This power of salicylic acid was then utilised, to determine whether it would also prevent infection if mixed in a concentrated form with such poisonous matter as tongue-scrappings. It was found not to have any effect upon the matter, and the lesions, though without bacteria, appeared as usual. These experiments, says Dr. Satterthwaite, suggest that salicylic acid and carbolic acid, while excellent preservatives and antimiticophytics, are perhaps not disinfectants at all in the strict sense of the term.

The following are the general conclusions at which Dr. Satterthwaite feels warranted in arriving.

1. Bacteria are certain vegetable organisms which belong probably to the algæ; they are found abundantly in nature, but chiefly where there is moisture.
2. They exist in the body in health, covering the mucous membranes from the mouth to the anus, and sometimes appear to penetrate a certain distance into the system, without causing symptoms of disease.
3. They also exist in putrefying fluids, and in various diseased processes, occurring in hot and cold abscesses, in the blebs of erysipelas, and in simple blisters.
4. It is doubtful whether the virulent principle of infective disease is albuminous.
5. This principle does not reside in the perfectly clear fluid which passes through porous clay. In putrid infectious fluids, this appears to be certain. The poison is rendered less virulent by repeated filtrations through common filter-paper.
6. The virulent principle may be boiled for hours, filtered numbers of times in the ordinary way, boiled with alcohol, and again filtered and dried, and yet the watery extract of such a dry residue will produce septic symptoms. It is therefore soluble, or at least suspended in water.
7. The liquid, which is thus poisonous, may be clear to the eye, but contains granules under the microscope.
8. These granules have not produced bacteria in a number of instances when they are placed in a suit-

able condition to do so. 9. We cannot, therefore, feel that satisfactory evidence has been brought forward to show that in any of the diseases or processes enumerated (anthrax, or carbuncular diseases of the French, sheep-pox, small-pox, typhoid and relapsing fever, etc.) minute organisms are the sole and sufficient causes of disease.

W. DOUGLAS HEMMING.

DRAKE ON DIAPHRAGMATIC HERNIA AND INTESTINAL PERFORATION.—At a meeting of the New York Pathological Society, on September 22 (*Medical and Surgical Reporter*, October 16), Dr. F. R. S. Drake presented a specimen of ulceration of the intestine, and protrusion of the omentum through the diaphragm, with the following history. A mason, aged forty-two, had been knocked down two years ago, while he was working, forcibly flexing his knees against the chest; after that he vomited blood several times, and complained of pain on a line with the lower border of the ribs, on the left side. He was received into a hospital, where he remained four months; after this, he could perform light work only. On August 24, while at work, he was seized with griping pains, and on the 27th was admitted to Charity Hospital. The abdomen was distended with gas, but no tenderness on pressure at any point; the bowels were constipated; pulse normal, and no fever. He remained in this condition for three days. On August 31, he was taken with nausea and vomiting, and complained of intense pain in the left hypochondrium, shooting to the right iliac fossa; the tympanites increased. He died on September 2. At the necropsy the intestines were found matted together, and covered by a fibrinous exudation. The abdominal cavity contained a large amount of faecal matter. A portion of the omentum had protruded through the diaphragm into the pleural cavity, and had become strangulated. The intestine had been intensely congested above the constriction, while ulceration and perforation of its coats existed below. The pleural cavity contained four ounces of fluid.

RODGERS ON A SUPPOSED TESTICLE REMOVED FROM THE VAGINA OF A HERMAPHRODITE.—Dr. L. Rodgers reports in the *Cincinnati Lancet and Observer*, for September, the case of an unmarried woman, aged thirty-eight, from whose vagina a tumour was removed, which was afterwards found to present all the natural characteristic constituents of a testicle. The individual in question was hermaphroditic, and is described as follows. She is of medium size, weighing one hundred and thirty pounds; her voice is quite husky, resembling that of a man; sallow complexion; face is devoid of hair. The mammary glands are absent, while the breast is thickly set with hair. The mons Veneris is thickly covered with hair, the labia majora and minora are well developed, and the vaginal orifice is comparatively small, scarcely admitting the introduction of a female catheter. The clitoris is absent, and occupying its position is a fully developed penis, excepting the absence of a prepuce. The penis, in the flaccid state, would measure about three inches in length and one in thickness. It is, however, curved downward, there being a web-like membrane extending from the glans to the upper junction of the labia majora, along the under side of the penis. This membrane is about a line in thickness, and arises from the root of the penis like a round cord, and then

spreads out like a fan, being attached as above stated. The patient stated that when the penis becomes erect this fan-like membrane draws the penis down, with the glans pointing toward the vaginal orifice. The tumour was attached by a long pedicle to the root of the penis.

MEDICINE.

LEHMANN AND DEVENTER ON ULCERATIVE ENDO-ARTERITIS OF THE PULMONARY ARTERY.—Upwards of six columns of No. 49 of the *Berliner Klinische Wochenschrift* (December 6, 1875) are filled with notes and remarks on the following case. The authors (Dr. W. L. Lehmann and J. Van Deventer, of Amsterdam) justly remark that ulcerative endocarditis has hitherto been almost exclusively observed in the left heart, especially on the semilunar valves of the aorta. This case occurred exclusively in the pulmonary valves. The patient, L. G. Lippenga, was forty-six years of age. He was a day labourer, and was admitted on March 21, 1875, into Professor Hertz's wards. He had enjoyed good health, and dated his present illness from eight or nine days before admission. It began with a rigor and severe pain in the side. He was feverish, had much dyspnoea, and expectorated rusty sputa. On admission he presented the physical signs of an acute croupous pneumonia of the right lower lobe undergoing resolution. The spleen was slightly enlarged. There were no other symptoms. His pulse was 88, and his temperature only 38.5°C. (101.3°F.)

A favourable prognosis seemed justified; and, in fact, on March 26 his temperature was normal, the dulness had considerably decreased, and high-pitched vesicular breathing, with copious moist crepitus, was heard. The patient felt well, his appetite was good, and he seemed on the point of recovery. After four or five days a relapse set in. His temperature reached the former point in the evening, whilst it remained normal in the morning. He had a teasing dry cough, and on April 2 pleuritic exudation was diagnosed on the right side. By April 10 the line of dulness reached the third vertebra behind and the fourth in front. The morning temperatures varied from 99.5° to 100.1° F., and the evening from 100.4° to 101.4°. Pulse 80 to 90. Respirations 45 to 48 in a minute. The urine appeared normal. On account of great dyspnoea (R. 56 per minute), about 600 c.c. (= 21 oz.) of thick, purulent, offensive pus were removed by Dieulafoy's aspirator. Febrile symptoms supervened, and on April 15 the dulness was even greater than before. On the 17th paracentesis was repeated, for urgent dyspnoea. Only about 4 oz. of pus escaped, though the cannula was pervious and moved freely in the pleural cavity. From this time he declined visibly, though his temperature did not exceed 102.2°. He had no rigors, and died on April 21 with symptoms of collapse, without presenting any objective or subjective signs of any cardiac affection. At the *post mortem* examination there were firm adhesions of the pleurae on both sides. There was nothing special in the left lung. The right lung was extremely collapsed. The space between the lower edge of this and the diaphragm was filled with yellow purulent fluid smelling like garlic (about 1,200 cc. = 42 oz. nearly). This space was divided into two by a vertical fold of the thickened pleura, which ran the whole length of the thorax. This accounted for the failure in the second puncture. The heart was slightly displaced to the left. The heart was somewhat hypertrophied, especially on the right side. Except a little brownish fluid in the pericardium, that membrane was normal. All the valves were competent, so far as could be tested by pouring in water. The aorta and its valves were normal. The pulmonary artery was for the most part obstructed by conical fibrinous plugs, of which there were five altogether, attached to the pulmonary valves, and extending into the vessel. The largest of these clots was one inch long, one-third of an inch wide where adherent, and about half an inch at the top. The semilunar valves preserved their form, but were rough, and the edges and fine surfaces were so ulcerated as to be transparent in many spots. The tissue was very fragile and rotten. The inner coat of the pulmonary artery showed, in the neighbourhood of the valves, equally distinct greyish-red ulcers, with sharp, white, undermined edges. Beyond this there was smutty-brown staining. There were some thrombi in the vessels of the left lung, which was greatly congested. In the bronchi of the collapsed [right] lung there was some pus. The spleen was somewhat enlarged. The liver enlarged and nutmeg-like. The remainder of the organs presented nothing very remarkable, though the brain was rather soft, and the kidneys congested. There was an infiltration of pus-cells or lymphoid elements through the whole thickness of the pulmonary valves when examined by the microscope. The cells of the inner coat were partly swollen [by imbibition?], whilst many had undergone fatty degeneration. Some of the cells were embedded in

fibrinous threads connected with the coagula. There were also, close to the coagula, heaps of globular, highly refractive, but for the most part very minute, bodies, which exhibited no movements. The pus-cells in the clots and valves were filled with these little bodies, and thus had the appearance of compound granule-cells. Reagents and colouring materials affected them little, nor could it be clearly made out that they increased in number. The muscular structure of the heart had undergone considerable fatty degeneration in many parts. Other portions exhibited brown induration. The pericardium and the rest of the endocardium were healthy. A few of the little bodies named above were found in the blood, and a great many in the fluid in the pleural cavity. Similar corpuscles were found in the tubuli uriniferi. The case was thus one of pyothorax, or empyema, with ulcerative endocarditis of the pulmonary artery only. This is extremely rare. Indeed, the right heart is seldom attacked. Sperling (*Ueber Embolien bei Endocarditis*, Berlin, 1872, and Schmidt's *Fahrbücher*, 1873, Bd. 159) has collected all the cases which occurred in the Pathological Anatomy Institute at Berlin from 1868 to 1870, and amongst 300 cases found only three affecting the right heart. Virchow (*Ueber Chlorose und Endocarditis puerperalis*, Berlin, 1872, p. 18) says that 'Endocarditis almost invariably affects the left heart—generally the mitral valve, then the aortic orifice, or both together, sometimes the tricuspid. The pulmonary artery seems altogether to escape.' In this case no symptoms in life pointed to the valvular disease. There was fever, but never over 104° Fahrenheit. Nor was there any sudden rise of temperature. The spleen was enlarged; but this is common amongst labourers in Amsterdam. There was never any abnormal bruit; on the contrary, the heart sounds were clear all through. However, the absence of cardiac symptoms is not uncommon in these cases. [Rud. Meyer, *Habilitationschrift*, Zürich, 1870; Virchow and Hirsch, 1871, ii. p. 92.] As, for example, in the cases by Eberth, of Zurich, and Maier at Freiburg [Virchow's *Archiv*, Band 57, p. 228, and Band 62, p. 145]. The small, highly refractive bodies were probably micrococci, monads, &c., or they may have been organic detritus. The differential diagnosis between the two is often very difficult, as mentioned by Dr. Arnold Hiller [Virchow's *Archiv*, Bd. 62, p. 361]. In this case there was no coloration by iodine. It is much to be desired that some fresh aid to the detection of vegetable organisms may shortly be discovered.

W. BATHURST WOODMAN.

CRAWFORD ON A CASE OF CONSTRICTION OF THE COLON BY A WOUND IN THE DIAPHRAGM: SUBSEQUENT DEATH FROM OBSTRUCTION.—Dr. Crawford relates the following case in the report of the Lycoming County Medical Society (*Transactions of the Medical Society of the State of Pennsylvania*, vol. x. part vi.)

On October 7, 1874, Dr. T. Lyon and Dr. Crawford were called to see Mr. —, aged thirty-one, a man of fine physical appearance and general good health. On September 7, while at a friend's house, he ate very freely of grapes. That same evening he was attacked with violent colic, preceded by a chill and followed by fever, vomiting, and abdominal tenderness. The ordinary remedies for such cases were used by his attending physician, but afforded no relief. After a few days his condition became

alarming, and his family, living at Philadelphia, were notified. They came and brought their family physician, a homœopath. He stayed a few days, and while there had the entire control of the case. He left, assuring the friends the patient would be well in a few days; said he had been too strongly medicated. The patient had a quick, wiry, and weak pulse, furred tongue, tympanites of the bowels, and complained of nausea and great thirst. While examining the abdomen, a cicatrix was observed over the lower region of the left lung, the result of a stab he received twenty-one months before, and from which, it was said, he made a rapid recovery.

After his recovery from the wound, he was actively engaged in superintending a planing mill, and had no sickness till his present attack, except occasional colic, which yielded to the ordinary remedies. The diagnosis of the case was mechanical obstruction of the bowels, and, there being no stercoraceous vomiting, the obstruction was considered to be high up.

The treatment consisted of tonics, stimulants, and essence of beef, to sustain his failing strength; anodynes, to allay pain; and the injection of large quantities of tepid water, to overcome the obstruction. A long gum tube was introduced a considerable distance up his bowels, and repeated injections were used, yet nothing but water and mucus came away. He died on the night of October 8.

At the necropsy on the 9th, the peritoneum and a large portion of the intestines were found to be in a state of gangrene. The wound he had received twenty-one months before had passed through the cartilage of the eighth rib, entering the cavity of the chest, and had passed through the diaphragm to the left of the œsophageal opening, leaving a wound about one inch and a quarter long, through which quite a large loop of the transverse colon had passed, pushing up the lower part of the left lung and also the pericardium, to both of which the intestine was firmly adherent, also to the convex surface of the diaphragm. Eating the large quantity of grapes, the seeds of which could not pass the constriction, doubtless was the exciting cause of death.

ROSENBACH ON GRASS-GREEN SPUTUM.—No. 48 of the *Berliner Klinische Wochenschrift* for 1875 (November 29) contains a paper by Dr. Ottomar Rosenbach, of Jena, on what he calls 'a new variety' of grass-green sputum. He considers it to be totally different from that described by Traube (see Nothnagel's paper on green sputa in the same journal, No. 27 for 1864). The present sample was expectorated by a patient suffering from bronchial asthma with typical attacks of orthopnoea. After these attacks an immense number of pointed octahedral crystals were always found in the sputum, such as Leyden describes. Some of these crystals, on standing, had on previous occasions shown a slight tinge of green. This time the colour was first observed after standing twenty-four hours in a glass. The original colour was greyish-white, and the sputum was muco-purulent. Its reaction was neutral. Microscopically, the purulent masses were found free from colour, and the coloured fluid was found to consist of solitary spores, and larger conglomerations of small granules, refracting light strongly, apparently heaps of sporules. The outline of these masses was circular, the size varied a good deal. Acids, alcohol, and ether did not affect them. Caustic alkali deepened the colour. Some of the mucus,

pus, and epithelium cells exhibited minute granules, which resisted the reagents which broke up the cells. The fluid contained numerous and active vibrios. Some of the green sporules were successfully grown in milk, and in some phthisical sputa. Further attempts of the same kind on another occasion were less successful. [Some years ago, Dr. Barnes drew attention to the occurrence of green cryptogams (algæ or confervæ) in London milk, from the water used to dilute it or wash the cans—a probable source for the organisms noted above.—*Rep.*] W. BATHURST WOODMAN.

MORRISON ON THE USE OF ATROPIA IN OPIUM-POISONING IN AN INFANT.—Dr. S. W. Morrison writes in the *Philadelphia Medical Times*, November 27, that he was called on October 16, 1875, 5 P.M., to see an infant, aged four weeks, who had been given an indefinite amount of laudanum at about 10 A.M. of the same day. He found the pupils insensible to light; the breathing, nine respirations per minute; the extremities cold, and the child altogether insensible. The energetic slapping of its face with cold wet cloths also failed to arouse it. One drop of fluid extract of belladonna (Tilden's) was then given with a little aromatic spirits ammonia and brandy, and in a short time afterwards an electro-magnetic machine was made to operate on the child with all its strength, but without arousing it in the least. At 6 P.M., about forty minutes after giving the first drop of belladonna, thinking the child was about to die, he gave two drops more of belladonna, with more brandy and ammonia, and continued the electric currents. At 6.15 P.M., the battery began to arouse the infant, and he found its pupils soon after respond to light. Its recovery was then rapid and complete.

VOGL ON TYPHUS.—Dr. A. Vogl, army-surgeon in Munich, in a paper in the *Aerztliches Intelligenz-Blatt* for October, makes some remarks on typhus fever treated by cold water when the temperature had reached 39.5° Cent. (103.1° Fahr.) In the course of two years, fifty cases, as he says, came under his observation, and of these seven died, or 14 per cent., a mortality by no means favourable to the cold-water treatment in typhus, supposing, which we shall presently show to be very doubtful, that all, or even any of his cases, were typhus at all. Dr. Vogl paid particular attention to the temperature, and he found, what has been found by other German observers, that the temperature in fever does not, as is too often supposed, rise gradually to a maximum height in the evening and then fall to a minimum in the morning, an idea derived from the misleading practice of taking only morning and evening temperatures, but that the temperature in twenty-four hours forms a wave with two or more points or maxima (*Gipfels*) with corresponding depressions. In double-pointed waves (*Zweigipfligen Wellen*) the higher point was reached at 6 P.M., the lower occurred at 10 P.M. In three-pointed waves (*Dreigipfligen Wellen*) one height was reached at 10 or 12 in the morning, the second about 1 or 2 P.M. and the third or highest point (*Spitze*) at 6 P.M. In four-pointed waves the maxima were reached at noon, 2 P.M., 6 P.M., and 10 P.M., the highest point of all being attained at 6 P.M. The daily minimum was found to occur at 8 A.M. Dr. Vogel divides his cases into four groups. 1. Cases in which the crisis took place about the seventh to the ninth day; 2. Cases in which it took place on the fourteenth day; 3. Cases in which it was delayed until the

end of the third week; and 4. Fatal cases. The average temperature of all the cases, the average maximum temperature, the average remission, the absolutely highest temperature, and the absolutely lowest, are all given, with what useful object the present reporter fails to see.

This paper of Dr. Vogl's, however, is chiefly useful as showing the loose and inaccurate manner in which the word typhus is still in many quarters applied. Fifty cases of illness are somehow described in the article of which we speak, and they are called typhus; but in the notes supplied as an appendix, in no single case is there any mention of the well-known typhus eruption. In short, enteric fever, pneumonia, febricula, and, perhaps, typhus and other acute diseases, appear to be mixed up indiscriminately together. In proof of our assertion, we translate the notes of a few of the cases as follows.

1. For the first four days a high temperature of from 40° to 40.4° Cent. (104° to 104.72° Fahr.), which afterwards became more moderate, and fell on the seventh day. Pulse 104 to 120 on the first four days, then 84, on the appearance of defervescence 66. Great weakness; labial herpes on the sixth day.

2. High temperature for three days; fall on the seventh. Pulse for three days 100, then 84—92 up to defervescence; great general weakness; predominating lung-affection, especially on the right side.

3. In the first day, subcontinuous fever with exacerbations of from 40° to 40.8° Cent. (104° to 105.45° Fahr.) on the tenth day; on the last-named day the exacerbations and remissions fell; and on the twenty-first day collapse through peritonitis set in, and on the twenty-sixth day death occurred. Pulse 102 to 128.

4. Typhus on the seventh day of the fastigium interrupted by cholera. After two days' illness commencement of the acme on April 1; maximum of 40.8° Cent. (105.45° Fahr.) reached on the first day; type remitting, two-pointed curve; on the third day enlargement of the spleen was established; meteorismus, a few rose spots; slight bronchial affection, no delirium, great restlessness, three stools daily. On the fourth day restlessness, no delirium, erythema on the left trochanter region, increase of spleen. Pulse, from the first to the seventh day inclusive, 96 to 108. On the seventh day evening exacerbation of 40.1° Cent. (104.18° Fahr.) Pulse 96. Bronchial affection (muriate of quinine internally). During the night of the eighth day an attack of cholera with diarrhoea and vomiting, collapse, thready pulse, voicelessness, rose spots pale. On the ninth day continued diarrhoea, temperature 35.6° Cent. (96.08° Fahr.), suppression of urine, pulselessness up to the eleventh day after suppression of urine for sixty-two hours. *Post mortem* appearances corresponding to the algid stage of cholera; everywhere numerous typhus (*sic*) ulcers in the ileum with bloody edges, one of which had perforated the intestine, but was attached by the edges to the neighbouring intestinal wall.

ALEX. COLLIE, M.D.

ANDREWS ON FUNCTIONAL DISEASES OF THE HEART.—In the *Detroit Review of Medicine* for October is an original communication from Dr. Andrews on this subject. After reviewing the nerve-supply of the heart in all its bearings, he says:

From our present knowledge of the relations

between the heart and general organism, through the nervous system, it is easy to see how functional disorder may arise and become permanent without any recognisable lesion, or may be the precursor of grave organic change. The explanation of the frequency of nervous derangement of the heart's action in valvular disease, is also readily made through the morbid impressions transmitted from the brain when the blood becomes deteriorated. The general nervous excitability, often concomitant with inorganic disturbance, may be traced to the same origin. We may practically group these cases into three divisions, sufficiently distinct in phenomena to be easily separable, but at the same time probably dependent upon similar departures from the physiological state. Moreover, we may find in the same individual at different periods the symptoms characterising each of the states, and proving that in some instances the three divisions are the various stages of a progressive morbid condition. Many cases, however, could be cited where the characteristics of each class occur alone, with no previous or subsequent history of change of type.

The first of these groups presents cases mild in character, usually of recent origin, almost always in persons who have much overtaken themselves habitually, and where the blood has suffered rapid deterioration, it may be without much loss of body weight; or in those of feeble habit, who have been suddenly called on for severe mental or physical labour. This type is well illustrated among chlorotic patients and females of spare delicate habit, who are liable to sudden severe demands through their social relations. Females furnish by far the larger number of cases of this kind, though we may here include the form of functional disease first recognised and thoroughly analysed by Professor J. M. Da Costa, and occurring among soldiers most commonly, though also observed among miners, and, rather rarely, other mechanical workers; and among these cases we find instances where the disease assumes a severe character, and is attended by constitutional disturbance. The majority of cases comprised in this group are cured or much benefited by treatment.

The second division consists largely of cases in whom the phenomena just described have become chronic. The blood has become seriously impoverished through malnutrition, dependent upon some constitutional vice, or bad hygienic surroundings; generally the nervous centres, suffering also, show in various directions perversion of function, and the persons affected in this manner present a great variety of distressing symptoms referable to the general disorder.

In the third division may be included all those cases where indications of organic cardiac change are manifest, in connection with functional disturbance, either directly or remotely consequent upon this state; not referring those cases of cardiac disease to this class which have their origin in any inflammatory affection, but only those that arise in the obscure nutritional changes that usually manifest themselves first in nervous disturbances, but at length involve the blood so much that its impoverished state is unmistakable. The most common instances are those where long-continued malnutrition causes a tendency to fatty change, a lesion from which the heart most readily suffers, and which is soon followed by dilatation, and not unfrequently valvular disorders, directly due to weakening of the

muscular structures by the fatty substitution. Generally the organic changes are preceded by functional derangement of various kinds, which call the patient's attention and give rise to grave alarm. The physician is apt to regard this as unfounded; but he should bear in mind the danger of organic change where the assimilative powers are for a long time seriously impaired. It will be seen at once that all the predisposing causes are found in the course of many chronic diseases, as phthisis, Bright's disease, diabetes, etc., and, as a fact, this form of heart-disorder often complicates the later stages of these diseases.

A considerable number of cases occur, which seem to occupy debatable ground between the three general divisions, and hardly belong to either; but they will usually be found affiliated to one or the other when carefully analysed.

The classification adopted is somewhat arbitrary, and is chosen for convenience of description. At the same time, a natural pathological relationship will be found among the members of the several groups sufficiently clear, I think, to warrant the step.

MORRILL ON TYPHLITIS.—In the *Boston Medical and Surgical Journal* for October 7 is an article on the above subject, by Dr. Morrill of Boston. After relating a case, he goes on to say that the form of typhlitis in which the cæcum is the original seat of trouble appears to be far less fatal, and its course (favourable or otherwise) much more protracted, than when the appendix is affected. Of thirty fatal cases, in four only did the disease begin in the cæcum. These four cases all occurred in women, and he believes that this form of the disease chiefly affects female adults. The proverbial neglect of the sex to pay proper attention to the condition of the bowels (thereby favouring the formation of faecal concretions) probably accounts for the liability of females to this trouble. That pure cæcitis should terminate fatally far less often than when the appendix is at fault, we can readily understand. The higher organisation of the cæcum, and its consequently greater recuperative powers, render the chances of perforation much less than when the appendix is inflamed. Then, again, if the trouble originate in the lodgment of a foreign body, its facilities for escape are far greater in the cæcum than in the appendix. A case recently occurred in which a head of wheat that the patient (a woman aged forty-three) had inadvertently swallowed, after a lapse of six weeks was passed from the bowels, and the symptoms of severe inflammation of the cæcum at once subsided. Moreover, according to Bartholow, perforation very rarely takes place through the anterior wall, but makes its way through the gut posteriorly, and thus the immediate dangers arising from acute peritonitis are avoided. The appendix, on the other hand, is retained in its place by a fold of the peritoneum; and this accounts for the rapid development of acute inflammation of its membrane when the seat of the trouble is here. As a rule, cæcitis is slow in its development, and lacks the marked symptoms which are usually present in the other form of the disease. It is usually in cases of this kind that faecal abscess occurs, ulceration of the appendix often ending fatally before pus has a chance to form or to come to the surface. Moreover, an ulcer perforating the posterior wall of the cæcum comes at once upon cellular tissue, and an abscess

is very apt to be the result. That such a collection may be absorbed, and often is disposed of thus, we have abundant evidence. The pointing or rather opening of such an abscess externally is much rarer than one would naturally suppose; in forty-two fatal cases it was observed but twice.

SURGERY.

RODDICK ON A CASE OF FRACTURE OF THE EPIPHYSIS OF THE GREAT TROCHANTER: PERIOSTITIS: PYÆMIA.—In the *Canada Medical and*

Surgical Journal for November Dr. T. G. Roddick, Professor of Clinical Surgery in McGill University, states that on July 4 he was called to attend a lad, H. P., aged sixteen. He found him lying in bed on the right side, and suffering very considerable pain in the lower part of the left thigh and knee, with an aching sensation over the gluteal region. As to the origin and history of his ailment, Dr. Roddick could elicit nothing very definite beyond the following. He had been limping about for three or four days in the previous week, complaining of soreness in the limb, which was attributed to an ill-fitting boot. On July 1, while standing at a desk in an office, he was suddenly seized with an excruciating pain in the left hip, and was taken home in a cab and placed in bed. After a few hours' rest he became much relieved, and on the following day he limped about the house with comparative comfort. On July 3, however, he could not get about without assistance. He had always been exceedingly active, outstripping the majority of his comrades in running, jumping, etc., and on or about the day his lameness became noticeable, he had an indistinct recollection of spraining or twisting the affected limb while hurriedly leaping a fence in pursuit of a ball. He limped through the remainder of the game, but next day thought little of the accident. There was no special pain complained of on pressure over the region of the hip-joint, nor indeed in any other part of the limb. Dr. Roddick, therefore, was disposed to look on the case as being neuralgic, and administered a hypodermic injection of morphia, and gave instructions to foment the thigh with hot water and give a dose of senna.

On July 5 he was much relieved by the hypodermic injection, and had passed a comparatively comfortable night. There was, however, some pain on pressure, and slight swelling over the outer side and front of the thigh, and on moving the limb the pain was decidedly greater in the neighbourhood of the hip than before. The presence of swelling with pain on deep pressure led Dr. Roddick already to suspect periosteal inflammation. There was also now marked constitutional disturbance, as evidenced by the coated tongue, rapid pulse, 110, and slight headache. There was swelling of the parotids, especially of the left side; also slight pain in the right ankle and great toe, with a small patch of redness over each, but no apparent swelling in either. Dr. Roddick ordered hot poultices to the entire thigh, and internally powders containing five grains of Dover's powder, and half a grain of calomel every four hours. He had a slight rigor during the night, and next day the sides of the face were more swollen, the pain in the ankle and toe were worse, and the redness was more extensive. The swelling in the thigh was more marked, and Dr. Roddick plunged an exploring trocar into the thigh, striking the femur on the outer side, and about the junction of its upper and middle third. A quantity of unhealthy looking sanious pus flowed through the cannula. He now gave the patient chloroform, and followed the exploratory puncture with a long and deep incision, down to and through the periosteum. This was followed by probably half a pint of the same kind of pus. The wound was plugged to the bottom with oiled lint, and poultices of linseed meal applied. He prescribed also a grain of quinine, twenty minims of the tincture of iron, and five grains of the chlorate of potash in mixture every four hours, together with beef-tea, milk, and wine *ad libitum*. He was very comfortable after the operation, and slept well. On

the 7th his pulse was 120; temperature, 102°. The tongue was inclined to be dry in centre; he had had two rather relaxed stools. Dr. Roddick injected the wound thoroughly with a weak carbolic-acid solution as the discharge continued to be very profuse and fetid. On examining the bone with his finger passed through the wound, Dr. Roddick found a large surface of bare bone extending upwards towards the neck of the femur. Almost coincident with the removal of the pus by the incision, the parotid enlargement and pains in the joints of the great toe and ankle began to subside, so that in twenty-four hours the face had almost resumed its original appearance, and the patient could move the affectedoints.

On July 8 the parotid swelling had entirely disappeared, and the ankle and great toe could be moved as well as ever. The pulse was 124, and small in volume; temperature, 100.75. The patient had a quarter of a grain of morphia during the night which gave him a refreshing sleep. The discharge from the thigh continued to be large in quantity, and of a most offensive odour. Dr. Roddick repeated the carbolic-acid injection, of which, as before, a large quantity was retained, indicating the existence of a large cavity.

On July 11 the condition of the patient was more unfavourable. The pulse had ranged from 120 to 130, and the temperature from 101½° to 103° at night. The discharge continued to be profuse, and the patient's strength was rapidly running down. Dr. Fenwick met Dr. Roddick in consultation, and after a careful examination of the case agreed with him in the diagnosis and course of treatment, but suggested the introduction of a drainage-tube. Dr. Roddick proceeded immediately, under chloroform, to make a counter-opening about four inches higher than the original one; and while in the act of passing his finger down to meet the probe bearing the tube he came across a fragment of bone, drawn far away from the shaft of the femur, which, on careful examination, was found to be the epiphysis of the trochanter major. As it was held firmly by the muscles inserted into it, and was evidently at that time doing no material harm, it was left. The drainage-tube was introduced, and subsequently did good service in carrying off the rapidly accumulating blood and pus. The patient gradually sank, and died on July 17.

Thirty-two hours after death, assisted by Dr. Cameron, Dr. Roddick cut down upon and removed a large portion of the diseased femur, with the unattached epiphysis of the trochanter major. The periosteum was separated from the bone down nearly to the junction of the lower with the middle third; for that distance the femur lay in the centre of an immense abscess, the lining membrane of which corresponded to the periosteum. The detached epiphysis was almost completely denuded of periosteum, so that it could be removed from its muscular attachments with little difficulty. Owing to the opposition of friends, the examination was not further continued.

Dr. Roddick remarks that this case is almost unique in kind and occurrence. Professor Hamilton, in his work on *Fractures and Dislocations*, says that, so far as he knows there is only one 'well authenticated example' of fracture of the epiphysis of the great trochanter on record, viz., a case reported by Mr. Key to Sir Astley Cooper.

As to the cause of the accident, Dr. Roddick

thinks that the fracture must have occurred from muscular action, when the lad leaped or threw himself from the fence in pursuit of his ball; and that, the process being firmly held by the tendinous expansions covering it, he was able to walk with comparative ease for several days, until these suddenly gave way, either from ulceration or periosteal effusion. None of the ordinary symptoms of fracture were found at any time.

The other points of interest in the case were the unmistakeable signs of blood-contamination, as evidenced in the enlarged parotids and painful joints, which, however, disappeared with remarkable rapidity as soon as the periosteum was opened and the pent-up pus dislodged. It is more than likely that had the incision been delayed many hours longer, the pyæmic symptoms would have made such headway as to have got beyond all control, and life would have been destroyed much more rapidly than was ultimately the case.

FORSTER ON A NEW METHOD OF PREPARING PLASTER OF PARIS BANDAGES.—Dr. E. J. Forster (*Boston Medical and Surgical Journal*, October 7, 1875) remarks that the common method of preparing plaster of Paris bandages, by rubbing the plaster into the bandage and rolling it by hand, is tedious and untidy. The plaster is scattered about, even when the greatest care is exercised, and the sensation of handling the plaster is decidedly unpleasant. To simplify the preparation of such bandages, and to obviate the objections just mentioned, he had a tinsmith make a pan into which could be inserted the common bandage-roller. When the pan is partly filled with dry plaster and the bandage is rolled, the latter will

become covered with the plaster. The pan, with the roller inserted, is well represented in the cut. D shows the sliding part of the bottom (partially drawn out to bring it into view), which tightly closes the opening through which the roller is inserted. The bandage AC is inserted under the rods, and rolled a few times upon the spindle to secure it, as shown in the cut. A large spoonful of plaster is thrown into the pan and upon the bandage at A, and the bandage is then rolled; by keeping it taut, the rod at B, under which it passes, distributes the plaster evenly, and forces it into the meshes of the cloth. By the rolling, the plaster is applied to both sides of the cloth, and the coarser the latter is, the more plaster it takes up. The ease and neatness with which a bandage can be prepared by this method was demonstrated before the Boston Society of Medical Observation, January 4, 1875.

It has been suggested to Dr. Forster that the same apparatus might be used in the preparation of

starched bandages; the pan being filled with starch of the proper consistency, and the bandage rolled through it.

NEWMAN ON STRICTURE OF THE URETHRA IN THE FEMALE, AND ITS TREATMENT BY ELECTROLYSIS.—Dr. Robert Newman observes (*American Journal of Medical Science*, October, 1875) five cases of stricture, including four cases of organic stricture and one case of spasmodic affection. The author alleges that electrolysis and nothing else cured the strictures.

CASE I. Stricture in a syphilitic subject.—A no. 5 sound was passed into the stricture nearly one inch from the meatus, and there was tightly grasped. Dilatation was perseveringly tried without any appreciable effect. Details are not given. Electrolysis was resorted to.—A no. 8½ olive-headed metallic bougie was introduced into the meatus, and in two minutes was passed into the bladder, and immediately afterwards a no. 11 bougie was passed in the same manner.

CASE II. Stricture and granular urethritis.—A no. 11 metallic bougie was introduced and electrolysis employed. In four minutes the instrument passed into the bladder.

CASE III. Stricture from urethritis.—A no. 6 bougie could be passed. A no. 12 bougie was attached to the battery, and in four minutes could be moved freely in the urethra.

CASE IV. Strictures and fibrous band.—A very small sound was inserted with difficulty. A no. 6 metallic olive-shaped bougie was pressed against the meatus, and the battery employed during five minutes. 'By degrees this obstruction was overcome by the galvanic action and electrolytic absorption.' Further on he writes under the head of this fourth case, 'It is well known that the chloride of zinc has a great affinity for the albuminoids and gelatines. Now the mucous surface from which this bridle (the fibrous band) took its origin being of an albuminous nature, the zinc pole acted by the well-established law of chemical absorption, the albumen being absorbed, the deposit was detached from the walls of the urethra, the carnosity lay loose in the urethra, and was expelled by the *vis à tergo* of the urine.'

CASE V. was one of spasmodic affection of the urethra depending on an ulcer in the rectum.

[We can only ask, would not the steady pressure exerted, without the electrolytic apparatus, have produced equally good results?—*Rep.*]

JOHN CROFT.

SAYRE ON SECTION OF THE LATISSIMUS DORSI. In the *Philadelphia Medical and Surgical Reporter* of October 23, is a clinical lecture on lateral curvature by Dr. Lewis Sayre of New York, with an account of section of the latissimus dorsi for the relief of an obstinate case. He holds that rotation of the vertebræ goes on ere lateral curvature is instituted. After describing lateral curvature, he goes on to speak of its treatment. After going over the ordinary measures, he describes a corset used by him in such cases. It is made by having spiral springs, a few inches longer than the corset, quilted into pockets in the corset and forcibly pressed into these pockets, so that the corset is constantly making efforts to untelescope itself. As the patient is generally smaller at the waist than at the upper and lower extremities of the trunk, this corset is very

much like a double cone. It is placed upon the patient by first fastening the central point at the waist, and then the slope of the corset above and below. A patient was shown, slung by his shoulders, and by doing so the broad band of the latissimus dorsi was brought prominently into view, and the impossibility of drawing him straight without rupture, or section of it, was demonstrated. Any attempt at continued stretching produced reflex spasm of the muscle, and caused it to undergo stronger contractions still. Dr. Sayre then took a straight tenotome and made a subcutaneous section of the muscle, the fibres snapping as the man straightened up. The lateral curvature was straightened at once, and all the deformity left was the angle of the ribs on the opposite side. The man was put to bed, and secured by elastic bands so as to be perfectly straight. Three days afterwards (October 9) he expressed himself as highly delighted, and everything was satisfactory.

MATERIA MEDICA AND THERAPEUTICS.

BOUCHUT ON SURGICAL ANÆSTHESIA IN INFANTS BY THE ADMINISTRATION OF CHLORAL BY THE STOMACH.—Dr. Bouchut (in *Bulletin Générale de Thérapeutique*, October 30, 1875) gives a résumé of his communication made to the International Congress at Brussels.

He states that its action is certain and easy, and that like results cannot be obtained in the adult; it is the one new proof of the difference of action of certain medicaments in infants and adults. The latter cannot swallow without disgust and intolerance a sufficient dose to produce anæsthesia. In the infant, on the contrary, chloral is taken without difficulty in doses up to forty-five or sixty grains. It provokes neither pyrosis, gastritis, vomiting, nor diarrhoea, and it produces anæsthesia more or less intense. It is only after a considerable number of cases and a prolonged trial that Dr. Bouchut has communicated his experience. Chloral acts as a hypnotic and anæsthetic. He has frequently employed it in chorea, cerebral rheumatism, opening abscesses, and tooth drawing. In some cases he has continued its employment daily for a month. Out of 8,000 or 10,000 cases he has never had a fatal accident with it. He has given it up to ninety grains daily in the same subject continued for a month or six weeks, so that 3,000 grains or more have been absorbed.

Dr. Bouchut first proposed the employment of chloral in cases of chorea in 1869, and he has seen cases so violent that a fatal result was feared cured by forty-three grain doses night and morning, in one case continued fifteen or twenty days. Sleep and absolute insensibility have been obtained by a dose of forty-five to sixty grains administered at once.

The same result may be obtained by suppositories, but the rectum is more irritable than the stomach; at the end of three or four days the suppositories provoke tenesmus, heat, and irritation, necessitating their discontinuance.

The stomach is the best channel for the administration of chloral in infants. A quarter of an hour after the ingestion of the full dose anæsthesia commences, and is completed at the end of an hour.

In cases where the Vienna paste has to be applied to a nævus, or an abscess to be opened, or teeth to be extracted, chloral is indicated.

The infant groans and moves without waking during the operation, then falls again into a passive condition. On awaking a quarter of an hour later, it is unconscious of having suffered pain, and has been spared the fright of seeing the operator.

ARTHUR W. EDIS, M.D.

DAY ON A NEW DISINFECTANT.—The *Australian Medical Journal* for July, 1875, contains the report of the July meeting of the Medical Society of Victoria. Dr. John Day of Geelong read a paper, with experiments, in which he stated that he had long been endeavouring to find some agreeable as well as efficacious means of purifying and disinfecting the hands after making *post mortem* examinations, and for other disinfecting purposes; especially one suitable for those in attendance on sick persons suffering from infectious diseases. In all his experiments, he had always looked to oxygen in some form or another as the disinfecting agent. Ordinary oxygen is a weak agent in this way, and in the two

active forms of ozone and peroxide of hydrogen, it acquires a somewhat disagreeable odour. After trying various ways of disguising this, he at last succeeded as follows. On examining some of Rimmel's toilet vinegar at the request of a lady friend, he found that it gave the reactions of peroxide of hydrogen pretty freely. He thought it might possibly disguise the smell of the latter substance, and he found that it did so. He therefore mixed ethereal solution of peroxide of hydrogen (the so called ozonic ether) with toilet vinegar, in the proportion of a drachm to the ounce; and found that the combination was a most agreeable as well as highly efficacious disinfectant. Dr. Day states 'that there are two marked advantages to be derived from the combination of vinegar with the peroxide of hydrogen. In the first place, vinegar, in common with most acids, is capable of preserving peroxide of hydrogen; and in the second place it allows of this powerful disinfecting agent being used with soap, the free alkali of which, under ordinary circumstances, would decompose it, but when it is combined with vinegar no appreciable change is produced.' He recommends that, after attending persons with puerperal fever, or other infectious diseases, the hands should first be well washed and dried, and that this disinfectant should be used afterwards being well rubbed into the skin, like eau de Cologne, or any other perfume.

W. BATHURST WOODMAN.

ROUXEAU ON THE HYPODERMIC INJECTION OF QUININE.—In the *Journal de Médecine de l'Ouest* for June, 1875, M. Rouxeau describes a case of uterine congestion associated with quotidian intermittent, the principal symptom of which was a neuralgic pain in the right groin; the pain was exceedingly severe, and recurred with striking periodicity. Four grammes (sixty grains) of sulphate of quinine were administered within a period of forty-eight hours, without making any impression on the disease, although the usual physiological symptoms, such as buzzing in the ears, deafness, and considerable gastric irritation were produced. After another day had elapsed, fifteen centigrammes of sulphate of quinine with one centigramme of sulphate of morphia were injected under the skin at the seat of pain. The subsequent paroxysm was very slight, and a repetition of the injection on the next day completed the cure. The solution employed contained a very small proportion of acid, and did not give rise to any serious local irritation.

E. BUCHANAN BAXTER, M.D.

WARM WATER IN SURGERY.—In a report from the Bellevue Hospital (*New York Medical Record*) it is stated that in the treatment of contusions, etc., by immersing the parts involved in warm water, one great inconvenience has been the excessive swelling which usually occurs as the result of the immersion. This can be avoided by a very simple process, namely, freely oiling the parts before suspending them in the water.

In the case referred to another fact was illustrated, namely, that the pus covering the surface of a wound becomes coagulated, and in that manner may obstruct a discharge which should continue. It is important therefore to remove the limb from the water occasionally, and syringe out the openings which may communicate with any sinuses or pockets from which pus has been discharging, for it will not be dissolved and removed by the water alone.

BORACIC ACID IN SCIRRHUS OF THE BREAST.—A case of scirrhus of the breast treated at the Bellevue Hospital, New York, presents a point of special interest in relation to the dressing. The breast was removed in the usual manner, no axillary gland being involved; but after the operation the patient suffered severely from pain in and about the wound. This pain was very markedly relieved by applying cloths which had been wet in a solution of boracic acid. Pieces of muslin were dipped into a saturated solution of this acid, and then dried. Before being applied, they were dipped in water.

PSYCHOLOGY.

JACKSON ON TEMPORARY MENTAL DISORDERS AFTER EPILEPTIC PAROXYSMS.—Dr. Hughlings Jackson (*West Riding Asylum Medical Reports*) has written an article which illustrates in clear and in-

telligible language the fact that the public cannot possibly measure the responsibility of a criminal when accused of an act which he has committed when labouring under a nervous disorder, if the symptoms of such nervous disorder be only slight and obscure. We should recommend this article to the notice of those learned gentlemen who think that, because they have laid down a law, probably founded upon some fashionable popular prejudice, such law must necessarily be correct; and who in consequence, are in the habit of turning into ridicule medical experts in a court of justice, whose evidence is grounded upon the immutable principles of nature and disease.

Dr. Hughlings Jackson's position as physician to the Hospital for the Epileptic and Paralysed has afforded him unusual opportunities of studying those obscure cases which hover about the border-land of insanity, and especially of observing the mental conditions of patients labouring under the various forms of epilepsy.

Dr. H. Jackson divides his subject, although not in a formal manner, into four heads:

I. Cases in which eccentric or grotesque acts merely were observed.

II. Cases in which great complexity of action was found blended with the epileptic attacks.

III. Cases of medico-legal interest, but of no great importance as regards criminality.

IV. Cases accompanied with such violence as to render the patient amenable to law.

With regard to the first set of cases, in which the patient simply acts oddly, it is observed that such cases have an important *indirect* medico-legal interest.

It is convenient to have one name for all kinds of doings after epileptic fits, from slight vagaries up to homicidal actions. They have one common character—they are *automatic*; they are done unconsciously and the agent is irresponsible. Hence the term *mental automatism* is used. Dr. H. Jackson thinks it probable that there is a transitory epileptic paroxysm in every case of mental automatism occurring in epileptics before their mental automatism sets in, although he freely admits that occasionally no signs of a prior fit are discoverable.

Passing on to the condition after the paroxysm, it is found that it is duplex: (1) there is loss or defect of consciousness, and there is (2) mental automatism. In other words, there is (1) loss of control *permitting* (2) increased automatic action.

For medico-legal purposes it may be assumed either that mental automatism always occurs after, or that in some cases it replaces, an epileptic seizure.

As an example of the first group of cases—those where merely eccentric acts are performed—an epileptic is mentioned who, when in an omnibus, blew his nose on a piece of paper, presumably after a slight fit. When he got out he gave the conductor 2*l.* 10*s.* instead of the usual coppers. This man was subject to both little and great seizures. It is important to note that the 'form' of these actions was correct.

Next, in reference to the statement that highly compound actions can be done automatically—*i.e.* unconsciously—another case of great interest is reported.

Here the diary of the patient himself is quoted. He says:—'I felt symptoms of an attack, and sat down, I believe, on a chair against the wall. And here my recollection failed, the next thing I was con-

scious of being the presence of my brother and mother (who had been sent for, as they lived opposite); and I have since been informed by my sister-in-law that she came into the kitchen and found me standing by the table mixing *cocoa* in a dirty gallipot, half filled with bread and milk, intended for the cat, and stirring the mixture with a mustard-spoon, *which I must have gone to the cupboard to obtain.*

This case illustrates the fact that the slightest fit the more complex the automatism after it. What form a man's mental automatism will take depends, Dr. H. Jackson thinks, very much on what his natural disposition is. A savage and suspicious man would, when a fit had temporarily removed his highest faculties, more likely have killed some one than have mixed *cocoa*. And just as this poor fellow went to the cupboard for a mustard-spoon, so, had he been a savage man, he might have gone to another room for a poker when his sister-in-law came in.

Dr. H. Jackson next states cases with a criminal aspect, but essentially similar scientifically, in order to illustrate how the trifling cases bear. He begins with trifling crimes. He had a boy under his care who was subject to fits, beginning by a 'subjective' sensation of smell; he would turn pale. To use his mother's expression, he would often after the seizures go 'right out of his mind.' He was a shoeblack; and once after a seizure threw his blacking-box at a policeman. This was the 'crime.' For this he was taken before a magistrate, and fined five shillings. One evening after a fit he got into a rage, and said that a gentleman in the street had offered him five shillings to clean his boots. Later he was taken to a lunatic asylum.

Cases are next mentioned in which the patient's doings were violent, a separation which is arbitrary although convenient. The violence and outrageousness of the seizure depend doubtless very much on the natural disposition of the patient who suffers from the attack.

The following case is the one of the most direct medico-legal interest, which was under the surgical care of Mr. Rivington, and the notes of which were taken by Mr. Mercer.

On the afternoon of January 19, 1874, the patient, Emily A., aged thirty-five, was cutting bread for her children's tea, when she suddenly sent them all out of the room, and was found a short time after lying in a pool of blood with a deep gash in the left arm, which divided all the structures in front of the elbow, and laid the joint open. It was then found that she was out of her senses; she was at once brought to the hospital, and found to be in an excited and maniacal condition, and accusing people around of having caused the injury to her arm. After several variations in her mental state, she was at length discharged from the hospital.

A year later, January 10, 1875, Emily A. had had very good health since she left the hospital. She had had several 'fainting fits,' in which she lost her senses for a few minutes, but none of the spells of unconsciousness that she used to have. She had never harmed herself or anyone else, except on the one occasion when she came to the hospital.

This case shows that the mental automatism may be developed by suggestion, or altered thereby. She was cutting bread when, as may be supposed, the fit took her.

This able paper is concluded by a few appropriate

remarks upon the importance of hereditary influence being given its due value in medico-legal inquiries.

H. SUTHERLAND, M.D.

CLOUSTON ON APHASIA AND CHOREA IN GENERAL PARALYSIS.—Dr. Clouston (*Journal of Mental Science*, October, 1875) remarks that various nervous symptoms occur from time to time in the course of general paralysis that closely imitate many of the neuroses of sensibility and motion, such as neuralgia, amaurosis, locomotor ataxy, glosso-pharyngeal paralysis, hemiplegia, apoplexy, and epilepsy. In two cases the ordinary symptoms of aphasia were present for a short period in one stage of the disease. In the first the aphasia came on once soon after the commencement, when the motor and mental symptoms were very mild. The patient, a man, was not exalted or excited, and had had no congestive or epileptic attacks. The first signs of the disease were headache, dulness, depression, causeless fear and suspicion. About eight weeks after it was noticed that he could not speak properly when asked a question. He clearly understood and tried to answer, but could not. He could get out one syllable but no more. When asked the name of an article he could not give it or gave the wrong, *e.g.*, called a chair a hat. There was much tremor of the lips and tongue. Next day he was quite free, but a fortnight later on had another attack of similar character and duration, and then became silly and soon excited with exalted delusions. At the same time the right side became more paralysed than the left. In the second case the aphasia was complete, and occurred after an epileptiform attack in the beginning of the disease. When aphasic he knew what was said, nodded his head and looked pleased, but could not say a word. This lasted for a few days and then passed off. The motor paralysis was in no degree unilateral. The case of unilateral chorea happened in a lady with slowly advancing and mild symptoms of the disease. She could only go up or down stairs with difficulty, and mentally was in a state of happy enfeeblement. She had a congestive attack beginning with stupor, going on to convulsions of the right leg, arm, and face, with a temperature over 100°. The convulsions came and went for a few days, leaving the side paralysed when they were not present. When they finally disappeared the paralysis was complete, but in a few days the power of movement came back, first in the legs and then in the arms. When she moved her left arm it jerked about as in chorea, and when she tried to speak the muscles of the face and tongue on the left side twitched, while the articulation was that of a bad case of chorea. The choreic movements of the face have persisted. Muscles supplied by the seventh nerve are most affected, all the facial and masseters twitching. The sixth nerve is markedly affected, also the third; the fourth apparently is not. The glosso-pharyngeal and spinal accessory nerves are affected, as shown in swallowing. Her speech is inarticulate. The sensory nerves and the pneumogastric do not seem to be affected.

G. FIELDING BLANDFORD, M.D.

WINTER ON A CASE OF NEW FORMATION IN THE CEREBELLUM.—Dr. Winter, of Brandenburg (*Berliner Klinische Wochenschrift*, September 13, 1875), relates the following case.

A cuirassier, twenty-four years old, strong and hearty looking, was admitted into the garrison hospital at Brandenburg, complaining of pain in the back of the

neck and head; otherwise he was healthy. At the age of eighteen he had four epileptic fits.

The condition complained of was attributed to rheumatism, till the patient was one day suddenly seized with vomiting. After remaining some few days in the hospital, the patient was heard screaming and groaning in the night. He was found dead in his bed shortly after this commenced. Throughout his illness there was no other symptom of importance. The illness only lasted three months. On opening the skull and carefully dissecting the brain, there was found attached to the pia mater, just above the atlas, a bladder of yellowish coloured fluid, which pushed aside the medulla oblongata towards the left. It extended upwards and outwards to the lobus biventer and tonsil of the cerebellum on the right side. Connected with this bladder, and lying on the surface of the lobus biventer, was a tumour of the size of a bean, resembling, on section, a lymph-gland. This tumour was not attached to the cerebellum. The entire right hemisphere of the cerebellum fluctuated as a partially filled bladder. On section it was found to consist of two large cysts, separated by a medullary partition, covered with a smooth white fibrous membrane. These cysts contained a clear yellow fluid, apparently homogeneous. The ventricles were all distended with a similar fluid. In the floor of the third ventricle was a small mass of exudation of the consistency of organised lymph. The remaining organs were healthy. From these appearances, the disease was regarded as one of cysto-sarcoma arising from the pia mater, affecting first the cerebellum, then the medulla oblongata. The case is remarkable as, notwithstanding the extensive lesions found after death, including the entire destruction of the right half of the cerebellum, there were no symptoms except of a complex negative description during life.

VOELKEL ON A CASE OF TUMOUR OF THE BRAIN. Dr. A. Voelkel (*Berliner Klinische Wochenschrift*, Nov. 8, 1875), after noticing the rarity of non-tuberculous tumours in the brain of children, gives the following case.

Caroline B., aged nine years, an intelligent, strong, and healthy looking child, in the beginning of February, 1875, had a sudden and severe attack of vomiting, followed by internal strabismus of the left eye. On the 15th of the same month she had another attack of vomiting; this time, accompanied by pain in the left side of the head, with some left facial paralysis, and a certain amount of double vision.

On February 24 this condition of affairs was increased.

The patient rapidly became worse, and, after some severe convulsions, died on April 2.

On opening the skull, the vessels on the surface of the cerebral hemispheres were found charged with blood. The arachnoid sac contained a considerable quantity of serous fluid. Loosely attached to the left side of the pons Varolii, was a roundish tumour nearly attaining to the size of a hen's egg. It was of a light brown colour. On microscopical examination, this tumour was found to be a specimen of what Virchow has called myxosarcoma.

The author, in conclusion, remarks that the case is interesting on account of the age of the patient, and the fact that there was no disturbance either of the spinal nervous system or of the mental functions.

WEISS ON A CASE OF MENINGO-MYELITIS ASSOCIATED WITH ALCOHOLIC DELIRIUM.—Dr. Jacob Weiss relates the following case (*Allgemeine Wiener Medizinische Zeitung*, September 14, 1875). A baker, aged thirty-three, was admitted into the hospital on February 17, suffering from alcoholic delirium. He had taken a large quantity of alcohol. At first he was sleepless, but sleep came on gradually after about seventy-two hours, and the patient seemed to be recovering. On the 28th, however, he was obliged to keep his bed on account of giddiness and inability to stand. The pulse was accelerated. On March 3 he was still unable to walk or stand without help. There was an increased reflex action of the lower extremities, with hyperæsthesia of the upper, and paralysis of the sphincters. There was also inability to extrude the tongue. This condition continued, and the patient became worse, a state of stupor supervening till March 9, when he died. At the necropsy the pia mater of the brain was much congested; there was acute internal hydrocephalus, with some toughness of the brain-substance. On the side of the left cerebellar hemisphere, the vessels were injected, and the pia mater much thickened. The pia mater of the spinal cord was also thickened in some places, particularly at the cervical enlargement. The substance of the cord in the cervical enlargement was softened, and in some places diffuent; lower down the consistence was normal. The heart was fatty, the liver was enlarged, and there was slight steatosis of that organ. [The record of the above case is of very little practical value, because the account of the necropsy, which is given in the author's words, is incomplete, there being recorded no microscopical investigation either of the brain or cord. The reader is left to imagine the condition of the nervous elements and of the vessels, being simply informed that in certain places the cord was softened, the brain 'tough,' and the membranes thickened. No mention is made of the quantity of fluid found in the ventricles as proving the hydrocephalus.—*Rep.*]

OBSTETRICS AND GYNÆCOLOGY.

HILLAS ON OVARIOTOMY WITH CÆSAREAN SECTION.—At a meeting of the Medical Society of Victoria in December, 1874 (*Australian Medical Journal*, February, 1875), Mr. Thomas Hillas related a case in which ovarian disease was complicated with pregnancy. He said: Mary M'C., aged twenty-four, single, was admitted to the Ballarat District Hospital, June 4, 1872. She believed that she became pregnant in March, 1871, and not wishing to be confined in the district in which she lived, she sought admission to the lying-in ward of the Ballarat Benevolent Asylum. She was admitted there in November, 1871, and after staying there until the following June, a consultation of the honorary staff was called, and she was discharged, her case being deemed ovarian dropsy, and not pregnancy. On her admission to the hospital she was examined by the resident surgeon, and subsequently by the honorary surgical and medical staff, all agreeing that she was suffering from ovarian dropsy, and that it was a suitable case for operation. On June 13, assisted by the honorary surgeons, Messrs. Nicholson and Whitcomb, and the resident surgeon, Mr. Owen, and the honorary medical staff, the patient being under chloroform, I commenced the operation by an incision midway between the umbilicus and pubes. On arriving at the peritoneum, I made a small opening into it, when out spurted a large jet of venous blood which the pressure of the finger controlled. I came to the conclusion I had wounded, unwittingly, a gravid uterus; and feeling sure of this, I extended the first incision upwards to the umbilicus, when a large uterus rolled out on to the thighs, and the ovarian sac protruded. This was tapped, and about eleven quarts of fluid were drawn off; there were but few adhesions, which were easily broken down, and there was no hæmorrhage. The sac contained about a dozen small cysts, but the external wound being large, there was no occasion to tap them. The pedicle was short and thick, and after being tied firmly with a double whipcord ligature, the clamp was securely applied, and the pedicle divided, the ends of the double ligature being tied over the ends of the clamp. Now came the difficulty. The uterus was all this time lying on the thighs, with a fetus in it, and a wound through its muscles, probably into the placenta. Some of the bystanders advised that the wound in the uterus should be sewn up, and that organ replaced in the abdomen; but seeing that labour must come on soon, and that rupture of the uterus would most likely occur at the seat of injury, I personally decided to perform the Cæsaean operation, as being the most likely means of giving the patient a chance to recover. The uterus was incised to about five inches, and the placenta and a fetus, alive, and well developed, at about the eighth month of gestation, were extracted. I then stitched up the wound in the uterus, with about nine or ten silver wire sutures, carefully tucking the cut ends down into the incision; immediately on completing this, the uterus contracted firmly. I then sewed up the wound in the abdomen with deep and superficial stitches, the deep stitches including the peritoneum, leaving the clamp at the lower margin of wound, and a good deal dragged upon. The right ovary was the one affected, and the patient measured sixty inches

round the abdomen before the operation. The sac and its contents, after removal, weighed thirteen pounds, and are preserved in the hospital dispensary. The patient vomited for about forty-eight hours after the operation, having been an hour under chloroform. This was relieved by morphia and ice, and on the fourth day all unfavourable symptoms abated. There was a discharge of pus from the lower portion of the wound, which ceased in about a fortnight, and then it completely healed. She was discharged, cured, at the end of six weeks. On July 3, a month after the operation, she menstruated moderately for four days, and again on August 28. I have seen her several times since, and she is in perfect health.

J. MILNER FOTHERGILL, M.D.

VINAY ON DYSENTERY IN LYING-IN WOMEN.—Dr. Vinay (*Lyon Médical*, August 15 and 22, 1875) gives ten cases collected chiefly from the Maternity Charity, at Lyons, during the summer of 1872, and from the private practice of M. Gignoux and M. Chambard-Hénon.

Of the seven hospital cases, who, with the exception of one, were all multiparæ, the patients were attacked, between the fourth and eighth days, suddenly with colic, straining, tenesmus, and generally bloody glairy stools; the majority had not any rise of temperature or alteration in the frequency of the pulse. In none were there any signs of hæmorrhoidal congestion; in two instances there was obstinate constipation. The treatment was in all cases a mild saline aperient, in the form of 'Eau de Sedlitz;' for the most part, the symptoms rapidly subsided under this treatment.

Of the four private cases, dysentery happened twice in one woman. In this instance there was no tenesmus, which is accounted for by the use of laudanum enemata at the onset. The other patients were primiparæ; and in one the labour was terminated by instruments. They all did well. It is worthy of notice, that in nearly all the cases the children were of unusual size; and in one half of the cases the occiput was posterior either to the right or left.

Dr. Vinay, in discussing the pathology of the disease, remarks how rare rectal affections are in parturient women, compared with vesical; this, he believes, arises from the former organ being less pressed upon, contused, and implicated both during gestation and labour than the bladder. The causes inducing dysentery in lying-in women he divides into predisposing and direct (*efficientes*).

The predisposing causes are:

1. Pregnancy, causing an increased flow of blood to the pelvis and a retardation to its backward flow.
2. Hæmorrhoids, above all internal. In most of the above cases there were old signs of this affection, but in none had the patients suffered from them during the pregnancies under observation.
3. Constipation, which is frequent during the latter stage of pregnancy, and for the first days after delivery.

Padzinski insists that prolonged retention of urine after delivery is the more serious in its after-consequence. Dr. Vinay considers constipation equally, if not more so. M. Béhier met with a case of numerous ulcerations of the rectum at a necropsy, where the patient had had the bowels confined for eight days after parturition. Virchow goes so far as to maintain that without fecal accumulation a true dysentery could not be produced.

The effective causes result exclusively from labour, especially difficult.

- a. Size of child; the majority were large children.
- b. Obstetrical operations, chiefly instrumental.
- c. Presentation of the occiput posteriorly to the right; in some of the above cases it was to the left. Nægelé showed that, when this variety of presentation occurred, the rotation of the head took place within the pelvis at the plane of the outlet. Of the seven cases noted in the Maternity, in four the occiput was posterior.

The symptoms were those usually noticed in dysentery. The third day was, as a rule, the day of attack; it was almost invariably preceded by constipation. It is noteworthy that at the time when these cases occurred in the Maternity, the sanitary condition of the hospital was extremely bad, septicæmia being frequent.

The tenesmus was the most painful symptom.

M. Laroyenne found the mucous membrane of the rectum much thickened in the cases on which he made a necropsy, but Dr. Vinay had never had an opportunity of making a *post mortem* examination.

The prognosis of these cases he regards as good; the best treatment is mild saline aperients, and careful guarding against prolonged constipation in parturient women.

ODEBRECHT ON INTRA-ABDOMINAL PRESSURE.

Dr. Ernest Odebrecht, of Freiburg (*Berliner Klinische Wochenschrift*, April 5, 1875), observes that Professor Hegar states that, under certain conditions not yet clearly made out, the hollow organs of the lower part of the abdomen are capable of aspiration when the body is in the recumbent position ('Suction Phenomena of the Abdomen,' *Archiv für Gynäkologie*, Band v. p. 177). He made two experiments upon a woman who had a tumour attached to the right side of the uterus, and who, after her delivery, was seized with peritonitis, which nearly destroyed the patient. Eight weeks after the attack, on drawing the urine off with a catheter, a noise like the suction of air up into the bladder was heard; and although there was some urine in the bladder, not a drop escaped by the catheter. A water-manometer was used to investigate this strange phenomenon. The following results were obtained.

1. The pressure in the bladder, measured singly, equalled two to three centimètres (water-column).
2. The pressure in the rectum, measured alone, was about equal to twelve centimètres.
3. On simultaneous measurement in the rectum and in the bladder, the pressure of the latter rapidly decreased on the passage of the manometer up the rectum.
4. Pressure on the bladder was considerably less when downward pressure was made on the posterior wall of the vagina.

The explanation is thought to be that the tumour became inflamed, causing peritonitis to be set up, which attacked the anterior surface of the uterus and the posterior wall of the bladder, which by the position of the tumour were pressed upon one another and became, finally, firmly attached together by bands of lymph, as also the adjacent abdominal walls to the fundus of the bladder. Consequently, forcible downward pressure would partially empty the bladder. Upon the cessation of this expulsive effort the fundus of the bladder would be lifted up by the abdominal

adhesion and stretched backward by the uterine, so that air could be sucked up.

A later experiment, when the woman had quite recovered, was not attended with any results.

Another case was that of a spare emaciated woman, aged thirty, with a fluctuating tumour about the size of a child's head at the bottom of the stomach. The writer succeeded in getting the woman to suck air once into the bladder through a catheter. Such a rush of air took place that it was heard by the operator, but all future attempts were resultless. The manometer in this case, when abdominal pressure was removed for a moment, indicated a fall of one or two centimètres, but not without manual pressure was applied.

STADTHAGEN ON EXTRAUTERINE PREGNANCY.—

A case of extrauterine pregnancy was exhibited by Herr Stadthagen before the Berlin Medical Society on February 3, 1875 (*Berliner Klinische Wochenschrift*, March 29, 1875). It occurred in a Jewess, aged thirty-eight, who had miscarried eighteen years previously through a fall. She had never been pregnant since. A tumour was made out, on her admission into the Jewish Hospital, in the abdomen, reaching as high as the umbilicus, and cognisable, *per vaginam*, in the anterior and posterior *culs-de-sac*. The uterus was pushed up against the sacrum, but not enlarged. Menstruation had ceased in September. There were no symptoms of morning sickness, nor enlargement of the breasts. On January 1 she exhibited signs of internal hæmorrhage, but recovered from it. On the 23rd she was suddenly seized with intense abdominal pain; she became gradually worse, and died on the 29th. A hæmatocele was suspected from the symptoms of internal hæmorrhage. The necropsy showed there had been repeated ruptures of the membranes covering the ovum, whence blood had escaped; and in the abdominal cavity there was a considerable amount both of recent and old-standing clots. The ovum was imbedded in a sac formed by the matting together of the small intestines, mesentery, and meso-colon of the sigmoid flexure. The right ovary was attached to the sac. The corresponding Fallopian tube was perfect, all but the fimbriated extremity, which seemed to be lost in the sac. The Fallopian tube was injured, and its canal somewhat narrowed; there being a slight contraction opposite the distal end. On the left side, the appendages were normal.

ALBU ON A CASE OF TUBAR PREGNANCY.—

Herr A. Albu reported, at a meeting of the Hufeland Society, a case of tubar pregnancy with sudden death, mistaken for a case of poisoning (*Berliner Klinische Wochenschrift*, March 22, 1875).

The woman was suddenly seized with sickness, diarrhoea, violent pains in the hypogastric regions, and repeated faintings. Up to the moment of being taken ill she was in perfect health. The catamenia had ceased for over two months. The abdomen was intensely sensitive to the touch, as also was the uterus. Poisoning was suspected, as she was living in concubinage. Shortly after Dr. Albu left her she suddenly collapsed and died.

The necropsy showed a rupture of the left Fallopian tube, whence the hæmorrhage proceeded. The membranes of the ovum were also torn through. The ovum was about the size of a walnut. Dr.

Albu observed that Maschka had already attracted attention to these cases of tubar pregnancy simulating poisoning by their suddenness, by tenderness and distension of the abdomen, by the extreme sickness and retching, pallor of the surface, small, barely perceptible pulse, collapse, cramps and convulsions, and unexpected sudden death. Herr Steinthal stated that Heim, in his admirable thesis on *Graviditas Tubaria*, related thirty-two cases, sixteen of which he had observed himself. W. C. GRIGG, M.D.

CAZIN ON CÆSAREAN SECTION IN CASES OF FIBROID TUMOUR.—Dr. H. Cazin (in *Archives de Tocologie*, December, 1875) gives the details in full of a case of this nature, filling up the pelvic cavity, where recovery ensued. He refers to twenty-one other cases, collected from various sources, where the operation was performed. He concludes that when a pelvic tumour occupies the cavity, and in consequence of its volume, or pediculation, or from adhesions contracted, cannot be displaced, where, in fact, the space remaining free is insufficient for the execution of other obstetrical manoeuvres, nothing remains but to practise hysterotomy.

It is difficult to establish a general rule. Each case must be treated upon its own merits. He thinks, however, that unless there are special indications, it is prudent not to temporise beyond twenty-four or forty-eight hours.

The line of incision must depend upon the position of the tumour and the axis of the uterus.

The proportion of children saved by Cæsaean section is sufficiently remarkable. Of twenty-two operations recorded, fourteen were living, three were dead before, and one died during the operation. In four cases the result is not stated.

Almost all the women were at full term, one only at the sixth, seventh, and eighth month respectively.

Only three mothers survived out of the twenty-two cases, death ensuing from exhaustion, hæmorrhage, or peritonitis. Professor Dupaul lately remarked that peritonitis killed twenty-nine out of thirty cases after hysterotomy; and on reperusing the cases, one is struck with the number of deaths due to hæmorrhage or collapse.

Whatever it be, the results of Cæsaean section in cases of fibroid tumours are deplorable.

Of the twenty-two cases recorded here, seven only were performed in Paris and other large towns, the remainder in the country and small towns. The want of success cannot, therefore, be ascribed to operating in the large towns.

It is in the condition of the uterus itself that we must seek for the principal cause of the mortality.

One has, in fact, to deal with a diseased organ, often for many years, having had sometimes to submit to many miscarriages, the irritation having extended to the peritoneum,—an organ which, apart from the previous aggravating circumstances, has suffered during the whole of the duration of pregnancy from the simultaneous presence of the product of conception and from the tumour, with a predisposition, so to speak, to inflammation.

The condition is far different from that where we incise a relatively healthy uterus on account of pelvic deformity. When the fibroid tumours are adherent by a large base, the portion of the uterus which is dilated for the lodgment of the foetus, weakened by excessive distension and a proportionate thinning, cannot contract after the operation and so encourages hæmorrhage; old adhesions to the

neighbouring organs contributing also to keep up the inertia.

In certain cases the hæmorrhage has been such as to necessitate compression of the aorta, sutures, etc., and may be directly credited as the cause of death in many cases, as well as indirectly of nervous accidents and collapse.

In some cases, where fruitless punctures as tentative operations had been attempted, which have not a little contributed to aggravate the situation, we must not credit the operation itself with the death resulting. ARTHUR W. EDIS, M.D.

QUINBY ON SPONTANEOUS CURE OF AN OVARIAN CYST BY DISCHARGE PER RECTUM ET VAGINAM.—Dr. Fred. Quinby, of East Jefferson, relates the following case in the *Detroit Review of Medicine* for December.

Mary S., aged forty-one, married, had one child twenty years of age. Her health, up to five years ago, had been good, with the exception of the menses, which were always very irregular, appearing at intervals varying from three weeks to three months; the discharge was sometimes scanty, at other times profuse. She first noticed a tumour about five years ago; it then appeared about the size of a hen's egg, situated in the left hypogastrium. It increased in size very slowly until about four years since, when the patient received a heavy blow on the affected side, after which the tumour grew very rapidly. No medicine was given throughout the period of growth, with the exception of opiates, which her extreme pain demanded.

Her abdomen last spring was as large as that of a woman at term. The physician in attendance, after consultation, decided that nothing short of ovariectomy would avail, which the patient consented to have performed. Last May, a short time prior to the day set for the operation, the woman, while engaged in household duties, experienced a sudden shock, or, as she expressed it, a 'giving way of something in the lower part of her belly,' followed by a profuse gush of a thick yellow and tenacious liquid, accompanied by a sudden diminution of the tumour. The discharge issued from both the rectum and the vagina, and continued to flow profusely for about four weeks, at the expiration of which time no trace of the tumour could be found. The woman is now, and has been for the past four months, able to do her own work, besides doing considerable work for other people.

DUROZIEZ ON THE INFLUENCE OF HEART-DISEASE ON MENSTRUATION, PREGNANCY, AND THE FÆTUS.—A series of articles on this subject, by M. Duroziez, is concluded in the *Archives de Tocologie* for November, 1875. Under the influence of this morbid state, menstruation is disturbed, sterility is possible, miscarriages are frequent, and premature labours often occur. The infant's life is jeopardised, either at the time of birth or a short time afterwards, the mother is threatened with death more or less rapid. On the contrary, patients suffering from heart-disease may be delivered without any grave accidents, and recover almost completely.

Occasionally the malady does not seem aggravated by pregnancy, and remains as it was without this complication. The treatment is the same as for other cases of heart-disease not complicated by pregnancy, but the new element necessitates the idea of another remedy—abortion or premature labour. In regard to the question whether one is authorised

in provoking abortion in a patient four or five months pregnant, presenting all the signs of severe heart-disease, which threatens life, and cannot but increase with the progress of pregnancy, no positive answer can be given. The dangers which surround the remedy itself are the cause of the doubts and hesitations, which perhaps the future will decide.

Again, in a patient advanced at least seven and a half months in a similar condition, is it necessary to provoke premature labour? Most practitioners incline to the affirmative. In fact, if art do not intervene, death is almost certain, both to the mother and the foetus. If art step in, there is less chance for the foetus, whose life is, however, seriously compromised already; but the preservation of the mother's life is more probable.

M. Duroziez thinks that, in all women affected with serious heart-disease, where the symptoms are general, premature labour should be induced; and even where there are no general symptoms, if there be other children living, it is a question whether labour should not be induced.

LUCAS-CHAMPIONNIÈRE ON THE UTERINE LYMPHATICS AND THEIR INFLUENCE IN UTERINE PATHOLOGY.—In the author's concluding article in the *Archives de Tocologie* for October 1875, he says that above everything must we bear in mind prophylaxis, and avoid the least local accidents to the neck of the uterus, not injuring it by unnecessary manipulation. Delivery once accomplished, it is well to see that the uterus be clear of putrid matters, but it is important not to irritate it.

Excessive cleanliness in the form of washing, injections, extraction of clots, is as harmful as excess of negligence. With the theory of puerperal poison, it will suffice to establish a current of water in the uterus to give a title to prophylaxis. Nothing can be more contrary to that which we every day observe.

When labour is prolonged, producing compression of the neck, or the vagina, it is wise to aid the forces of nature by the judicious and timely application of the forceps. When labour has been natural or terminated artificially, if any painful conditions arise, they ought to be attacked without delay. Revulsives and evacuates are here of great importance.

The value of sulphate of quinine against these conditions has been wrongly estimated, especially on account of too small doses having been employed.

[It is impossible to do more than very briefly indicate the author's conclusions. The articles are well worthy of perusal.—*Rep.*]

LEOPOLD ON THE HABITUAL DEATH OF THE OVUM AND ITS ARTIFICIAL EXPULSION; PATHOLOGY OF THE PLACENTA AND THE UMBILICAL CORD.—In a communication occupying sixty pages (*Archiv für Gynäkol.*, Band 8, Heft 2) embodying much original observation and literary research, the author, after fully discussing the subject in all its details, concludes that the habitual death of the ovum may be due to various causes; viz., *a.* Syphilis in the parents; *b.* Anæmia or blood-anomalies in the mother; *c.* Chronic disease of the uterus, or uterine irritation; *d.* A general individual irritability; *e.* Inherited disposition; *f.* Changes in the placenta and umbilical cord.

The rational treatment can only consist in obviat-

ing the cause. With this view antisymphilitic treatment, strengthening the system, curing local disease, etc., are the indications to be followed. Artificial expulsion of the ovum two weeks before the usual termination by death will often succeed in procuring a living child. The exact time for inducing labour must depend upon the condition of the foetus as evidenced by the examination of the foetal heart, assisted also by the history of previous pregnancies, and the probable cause of the premature death.

BARDY-DELISLE ON A CASE OF CÆSAREAN SECTION.—In the *Annales de Gynécologie*, November 1875, Dr. Bardy Delisle narrates an instance where the patient recovered; the child being extracted alive, and dying five days after birth from pneumonia.

The patient, aged nineteen, primipara dwarfish in stature, had a pelvis the antero-posterior diameter of which measured only five centimètres (1.965 inches), the sacrum forming a prominence in place of a concavity. Labour had already set in. Chloroform was administered. The usual incision was made; severe hæmorrhage occurred, but ceased after the extraction of the child and placenta, the uterus contracting immediately. The peritoneal cavity was sponged out and the wound closed by deep sutures; the peritoneum not being included. Feverish symptoms were present the first few days, but she convalesced perfectly.

The child, a male, well-formed and developed, progressed favourably the first three days, but succumbed to pneumonia on the fifth day, probably induced by exposure at an open window.

TARNIER ON THE EMPLOYMENT OF IODOFORM IN VAGINISMUS.—In the *Journal de Médecine et de Chirurgie Pratiques*, M. Tarnier relates a case of much interest where iodoform succeeded perfectly in relieving vaginismus.

A woman aged thirty-two, married seventeen years, was affected with an extreme hyper-æsthesia of the vulva, producing pain on walking, coitus being extreme torture. There was no lesion of the vulva or neck of the uterus. The vulval aperture and the labia minora were dusted over with iodoform powdered, and a few hours afterwards the parts were insensible. Coitus was effected with scarcely any pain. A tampon of cotton-wool covered with the powder was placed between the lips of the vulva, and succeeded admirably.

M. Tarnier also employed iodoform in a most intolerable fissure of the anus, which had resisted all the narcotics and astringents usually employed in such cases. After a single application the pain diminished considerably, and a cure was effected in a few days.

WILLIAMS ON THE MUCOUS MEMBRANE OF THE BODY OF THE UTERUS.—Dr. John Williams (in the *Obstetrical Journal*, November, 1875), states that in many different animals the mucous membrane of the body of the uterus possesses a very highly developed muscular structure; that is, a considerable portion of the thickness of the uterine wall is formed by muscularis mucosæ—a stratum of muscular fibre-cells resting upon a layer of areolar tissue named 'submucous.' The submucous tissue has not been found in the human uterus. The changes which take place from month to month in the uterus—that is, the removal of the so-called mucous membrane, and its renewal by proliferation of the superficial

laminae of the muscular wall, show that a portion of that muscular wall is muscularis mucosae.

Dr. Engelmann (see LONDON MEDICAL RECORD, December, 1875, pages 696-7), controverts this view, as a physiological improbability to which we can find nothing analogous in the human system; but, as Dr. Williams states, upon merely theoretical and insufficient data.

ARTHUR W. EDIS, M.D.

FRANCIS ON THE OBSTETRIC FORCEPS AS A TIME-SAVER.—In a paper recently read before the Massachusetts Medical Society (*Boston Medical and Surgical Journal*, July 1, 1875), Dr. G. F. Francis, after reviewing the opinions of Simpson, Beatty, Collins, and other well-known authorities, alludes approvingly to Dr. Hamilton's (of Falkirk) experience, and concludes that lapse of time in the second stage of labour brings increasing danger: secondly, that the forceps is not necessarily a dangerous instrument; and finally, that the experience of those who have used the forceps freely, to save time and avoid danger, is by no means unsatisfactory.

TAYLOR ON THE TREATMENT OF CONTRACTED PELVIS.—At a recent meeting of the New York Academy of Medicine, reported in the *New York Medical Journal*, Nov. 1875, Dr. Taylor said that, in the consideration of the treatment of contracted pelvis, he would divide the subject into two parts: first, that in which the contraction was from two and a half to four inches; and, secondly, that in which the contraction was from two and a half to one and a half inch. He proposed to consider only the first class of cases on the present occasion; and, in their treatment, he thought that craniotomy was not indicated for the delivery of the patient in the great majority of cases, but that the choice rested between the forceps and version. He presented two deformed pelves, one of which was known as the uniformly contracted pelvis, and the other as the flat pelvis. He presented also a foetal head delivered by the forceps, in which the indentation caused by the promontory of the sacrum was nearly an inch in depth. The notes of two cases were read. In one the pelvis was of the simple flat form, and not rickety. The patient was aged twenty-three, and an inmate of Bellevue Hospital. She was delivered in thirty minutes by means of version. The second case was one of uniformly contracted pelvis, in which the antero-posterior measurement of the brim was three and three-quarters inches. In this latter case the cervix was only slightly dilated; and, contrary to the opinion of the majority, Dr. Taylor introduced the forceps within the undilated os uteri, and delivered the head of the child with considerable effort. The forceps that he used was after the model of Ritgen, but it had an extremely narrow blade, measuring not over two inches in width. If the forceps proved unavailing to apply the requisite force, the woman might be safely delivered by means of version.

Dr. Taylor said that he was of opinion that induced labour at the seventh or eighth month, in cases of contracted pelvis, was in many occasions indicated for the welfare both of mother and child.

At a subsequent meeting Dr. Isaac E. Taylor said that he did not agree with Dr. Goodell, of Philadelphia, who maintained that the neck of a foetus would stand a tractile force of 150 pounds before it would separate from the head. In Dr. Taylor's hands several cases suffered decapitation, leaving

the head in the uterus when a force not equivalent to 150 pounds had been exerted. He was of the opinion, also, that the lateral diameter of the foetal head could be reduced one half-inch by the use of the forceps, and no special danger ensue. He thought also, in a similar manner, that the antero-posterior diameter could be reduced seven-eighths of an inch with safety. Dr. E. R. Peaslee was of the opinion that Dr. Taylor's position could not be controverted. The subject was one of the most difficult to understand in the whole range of obstetrics, and one in which there was the greatest diversity of opinion. Dr. Hanks related a case which bore on the subject under discussion. He was called to see a patient in January, 1869, in which labour had been in progress for six hours before his arrival. He waited for four hours, and no additional advance was made, though the vortex had entered the superior strait. He found the patient to have a flat pelvis; and, by the aid of the forceps, he delivered the woman, after two hours, of a still-born child. The patient in a few months again became pregnant, and at the end of the eighth month induced labour delivered a still-born child by means of version. The patient again became pregnant, and at the end of the eighth month he again induced labour, but proposed to use the forceps, believing it would be productive of better results. On that occasion, a child was delivered, which lived for a few days and died of inanition. The patient again became pregnant, but passed into other hands. She was delivered of a still-born child, and in a few days afterwards died of broncho-pneumonia.

GOODSELL ON THE TENSILE STRENGTH OF THE FOETAL NECK.—Dr. Goodell says, in the *Philadelphia Medical Times*, I saw the strength of the child's neck put to a crucial test, and the result amazed me. I frankly confess that had I not been an eye-witness I should have been a doubter. It was a case of a primipara with flat pelvis and a large but putrid foetus. After craniotomy had been performed, a further obstruction to the delivery lay in the bloated chest and belly. Before this second complication was recognised, each one of the four physicians present, including myself, took his turn at the forceps. From a natural rivalry, the traction thus necessarily made upon the neck of the foetus by three of us in succession was no child's play. But that made by the fourth gentleman exhibited so much power and originality, that I shall here describe it. He turned the woman over on her side, brought her hips to the edge of the bed, and applied Hodge's forceps. He next carefully tucked a sheet around the lock of the instrument, removed his shoes, sat in a chair, and placed one foot across the perinaeum, the other across the vulva. He then grasped the handles, straightened out his body, and pulled with all his might and main, making every muscle in his body quiver with the effort. Yet, in spite of the enormous strain brought to bear upon the neck of the child, it was simply lengthened out, but not broken. The cranial stump was brought down to the outlet, but it literally sprang back at every intermission of the traction. This behaviour of the head, or rather what was left of it, was in fact the first clue that led to the discovery of the obstructive size of the child's body.

BARRETT ON VICARIOUS MENSTRUATION PER RECTUM.—A case of vicarious menstruation per

rectum is related by Dr. E. C. Barrett, of Jerusalem, Virginia, in the *Virginia Medical Monthly* for December. He was called in 1868 to Miss A., aged about seventeen, whom he found to be suffering from an attack of bilious remittent fever. He found that his patient had habitually been the subject of a vicarious discharge of blood from the bowels in the place of the regular monthly catamenia, a peculiarity that had come upon her about the time of puberty. She had never menstruated before the discharge made its appearance; neither had she since. He had known her long before he was called to see her professionally, and, from her seeming perfection of development, with a remarkable voluptuousness of physique, coupled with a most cheerful temperament, he had no reason to suspect that anything abnormal existed. The discharge came on regularly once in every twenty-eight days, and lasted for three or four days.

She was subsequently married, and in due time was confined of a well-developed male child. Dr. Barrett attended her through the period of her confinement, and from the beginning of her lying-in to her getting up there was nothing which was not in perfect keeping with the usual laws of all healthy child-bearing women. The uterus passed through the various changes incident to child-bearing, and the mother herself furnished to her child all the elements of a healthy nutrition. In the course of fifteen months the vicarious discharge made its appearance again, and continued with its former periodicity and regularity till its cessation announced a recurrence of pregnancy. And thus she has gone on, alternating as above described, till she has now been the mother of three children.

OPHTHALMOLOGY AND OTOTOLOGY.

GAYAT ON VISION AT EXTREME DISTANCES.—It has long been a recognised fact that, although the method now in use for determining the *punctum remotum* is sufficient for all ordinary clinical purposes, yet a soldier who could read no. xx. at twenty feet, might be utterly unable to become a skilled artillerist or a picked rifleman. In fact, to be able to see an object at a certain distance, and to be able to distinguish it from another resembling it, are two very different things; and in order to formulate the conditions which determine visual acuity at great distances, Dr. Gayat (*Annales d'Oculistique*, September and October, 1875) instituted a series of experiments. In the course of these observations, which were made upon the vision of different individuals for extreme distances over water as well as upon land, it was invariably found that vision was more accurate as regards details of objects when looked at upon land; and although the boatmen who accompanied Dr. Gayat could always see better than he could when on the water, yet even their answers were more ready and more accurate when their sight was tested along the shore and when they were on land. Even when the water appeared perfectly calm, there was an almost imperceptible motion of the boat which interfered with the accuracy of vision, whether the observer was on the shore, or the object was on the shore, and the observer was upon the water.

The extreme range of vision possessed by savage people is a matter of common observation; and, in the case of the Arabs of Algeria, this has been attributed by Dr. Furnari to the fact that the refraction of their eyes is hypermetropic. In a second series of observations carried on over the expanse of the little Sahara Desert, it was found that the difference of visual acuity was very marked in different individuals who were supposed to possess the same average visual power. The principal causes of many of the differences appeared in the course of these experiments to be the intensity of light and the incidence of light, so that it made a great difference whether the object was directly illuminated by the sun or by diffused light; the colour of the object, and the uniformity or the irregularity of its surface, and its dulness or its metallic lustre; the position of the observer, or of the object, and the nature of the horizon, especially whether there were a background of houses or of trees, which would admit some comparison with the object. These observations make it abundantly clear, says Dr. Gayat, that the results of experimental inquiry differ widely from those obtained in this matter by mathematical calculation; and when we take into consideration the influence of habit and of education upon distant vision—so long, for instance, as a sailor can readily distinguish the mast of a vessel when a landsman can as yet see nothing—it must always be a matter of great difficulty, even if it be possible, for us to determine exactly the limit of vision for extreme distances.

CUIGNET ON XEROPHTHALMIA.—This curious affection of the conjunctiva, which appears to be comparatively rare in this country, is frequently met with in some other parts of the world; and espe-

cially is this the case in Algeria, where Dr. Cuignet was stationed for some years. In this colony, where granular ophthalmia thrives and works much damage amongst the poor Arabs and the destitute Jews, xerophthalmia is very common; and Dr. Cuignet has published the result of his experience in the *Recueil d'Ophthalmologie*, July, 1875. In his opinion, this condition is not a disease *sui generis*, but is merely the result of one or more different diseases of the conjunctiva; and he defines it as being a fibrous transformation of the conjunctiva and of the corneal epithelium, with thickening, opacification, retraction, and more or less complete loss of sensibility.

The affection may be partial, or it may invade the entire conjunctiva; it may be met with in two or three different stages, and in the two eyes of the same individual. As regards the two varieties of the affection which are mentioned by Wecker, viz. xerosis glabra and xerosis squamosa, Dr. Cuignet considers that the latter form occurs only in the cornea, and that if it be a variety at all, it derives its characteristics from the tissues in which it appears, while xerosis glabra affects the conjunctiva in preference. The mechanism of the affection appears to be as follows: after one or more attacks of some form of ophthalmia the tissues remain congested, and their blood-vessels increase in size and in number, so that infiltration and thickening of the parts ensue; as these changes progressively take place, the secretive organs become destroyed, and the surrounding tissues become dry and assume the nature of fibrous tissue; and as this last transformation occurs the eyelids become distorted, and their movements impaired, at the same time that the patient may become disfigured by entropium. Dr. Cuignet considers that the above changes are analogous to those which take place in the liver, and which are spoken of as cirrhosis. He does not agree with those who speak of xerosis as being due to occlusion of the lachrymal canals; and in his own experience he has met with these several causes: entropium, granular ophthalmia of long standing; repeated attacks of scrofulous ophthalmia; staphylooma of the cornea, and ectropium. In the two latter instances, however, the affection has assumed a partial form only; and he is quite unable to support the opinion of Vidal, and of some other authorities, which would trace the origin of xerosis to some local fault of innervation.

As regards treatment, Dr. Cuignet has little or nothing to suggest. In its earlier stages, and when the affection is partial, some benefit may result from treatment—as, for instance, by the removal of an entropium; but, in the majority of instances, the poor inhabitants who are the subjects of the extreme degrees of the affection will not, or at least do not, present themselves until all reasonable chance of any good resulting from treatment has long passed away.

AGNEW ON CANTHOPLASTY AS A REMEDY FOR CERTAIN DISEASES OF THE EYE.—The author (*Annales d'Oculistique*, Sept. Oct. 1875) considers that an operation, such as he here describes, is the best remedy for the various chronic affections of the cornea and of the conjunctiva; for all such cases, in fact, which do not readily yield to treatment of the ordinary kind. In his opinion it is extremely difficult, if not impossible, by ordinary means, to secure the absolute quiet and immobility of parts which are essential to the speedy repair of corneal ulcers, or to

the complete removal of corneal opacities. His method of procedure is as follows.

Anæsthesia must always be produced, inasmuch as the operation is a severe one. The eyelids are to be separated with the finger and thumb, and their outer commissure is then to be freely divided as far outwards as the conjunctival *cul-de-sac*; this may best be done by a pair of strong scissors; the wound is horizontal, and its length will depend upon the attachment of the conjunctiva. The upper eyelid is then drawn upwards and inwards, until the external tarsal ligament is put upon the stretch; the blades of the scissors are then pushed vertically upwards, and are made to include this external ligament close to its attachment to the orbital margin, and to divide it by one stroke; if the tissues be put properly on the stretch, this is easily done. The ligament of the lower eyelid is not to be touched, inasmuch as its division might lead to eversion of the tarsal cartilage, and so cause an ectropium. When all bleeding is arrested, three or four sutures are inserted, care being taken that they do not include the margins of the divided ligament. The immediate effect of the operation is to elongate the palpebral fissure, and to prevent the upper eyelid from exercising the same pressure upon the cornea as before. In a few weeks, there is nothing to be noticed except that the angle of the commissure is less marked, and that the eyelids are not so closely or so firmly adapted to the surface of the eyes.

Dr. Agnew has performed this operation in 191 cases, and he recommends it for granular lids with pannus and with ulcerative keratitis; it has proved of especial service in cases of recurring phlyctenular ophthalmia; and in extreme cases he advises that it should be done for acute purulent ophthalmia, as much as a method of depletion as to diminish pressure upon the cornea and the retention of discharges.

BOWATER J. VERNON.

GRUBER ON MYRINGITIS.—In the September number of the *Monatsschrift für Ohrenheilkunde* will be found a fairly exhaustive lecture on myringitis, by Professor Gruber, of Vienna. After mentioning the usual symptoms of the affection, he describes others which are rarely met with, affecting tissues close to the tympanic membrane or considerably removed from it, and which have their causes either in the real changes in these tissues, or must be explained by reflex action. The one he particularly notices is that described by Lincke, who mentions having met with patients complaining of a sensation which they likened to the fluttering of an insect before the ear, lasting for a short time, then passing away for days, and again coming. Professor Gruber has met, he says, with a patient who described this subjective symptom to him in the same terms. On examining the membrane of this patient, he satisfied himself, by closely watching the posterior segment, where a movable cicatrix was seen, that this segment moved regularly outwards and inwards. This continued for ten minutes, and, on its cessation, the patient said the subjective noise stopped. During the time of movement of the membrane, Professor Gruber was able to determine objectively, by auscultation, the noise complained of. He agrees with Lincke in believing the cause to be a spasmodic contraction of the tensor tympani. He says this muscle is liable to spasmodic contractions in other conditions besides myringitis; but does not particularise the affections in which they occur.

Gruber finds that 95 per cent. of the cases of primary myringitis which have come under his observation are combined with perforation of the membrane.

DERMATOLOGY.

BERNHARDT ON SCLERODERMA OF ADULTS.—Drs. Bernhardt and Schwabach publish the following three cases in the 47th no. of the *Berliner Klinische Wochenschrift* for 1875.

Case 1.—An unmarried woman, thirty-six years old, began to suffer from weakness in the legs, followed by swelling and stiffness of the fingers. There was no actual pain, except some headache, but an unpleasant feeling of cold and stiffness. When seen in October 1874, about a year after the symptoms began, both the hands were swollen, the skin white and somewhat livid in colour, smooth, hard and very cold to the touch. The backs were more affected than the palms. The fingers could neither be bent nor extended fully, so that the patient found great difficulty in playing the piano. The upper part of the chest as low as the fourth rib was in a similar condition, the skin being smooth, stretched so as to show lines like those of the abdomen after pregnancy, and incapable of being raised into folds; but here the colour was reddish. No other part of the skin was affected. The urine was normal, and the general health good. In December the ankles swelled for a week or two, still without albuminuria. At the end of January, 1875, there was no improvement, and the continuous galvanic current was then applied to the neck, and faradisation to the hands. By the autumn the hands were rather better but the induration of the skin had spread further on the thorax, nearly to the ensiform cartilage. The patient also found that it had become difficult to open the mouth, and in this condition she was at the time of the report (Nov. 1875).

Case 2.—A married woman, aged thirty-four, came first under observation in May, 1875. For several years she had suffered from cold and numbness of the fingers, with slight but obstinate sore places on the knuckles, and lately the fingers had begun to contract. The lower two-thirds of both arms above the

elbow, and both fore-arms, showed the characteristic appearance of scleriosis—the skin brownish-red, here and there covered with minute scales, smooth, tense and adherent. The hands were less affected, but the nails, especially of the right hand, were small, curved, irregular and brittle, and the entire ungual phalanx of the thumb was atrophied. In the other hand, the ulnar fingers were most affected in the same way.

[The report notices that in the left hand the ring finger is 'abnormally' longer than the index. According to Henle and Ward this would be *normal*, though Weber says the opposite. The fact is, that the relative length of the second and fourth digits varies; though in England at least, the latter appears to be usually the longer. See an article on the subject by Professor A. Ecker of Freiburg in Breisgau (*Archiv für Anthropologie*, Bd. viii. S. 67) quoted by Mr. J. C. Galton in *Nature* for November 4, 1875.—*Rep.*]

There were several small ulcers on the fingers, as well as scars of others which had healed. Except for the pain these occasioned, the patient would have been able to write and even dress herself; for the bend of the joints was in each limb the part least affected, and movement was only somewhat hindered by the surrounding induration of the skin. The skin of the face, especially about the mouth and chin, was dark and somewhat stiffer and denser than natural, so that the patient could not open her mouth wide. The sensibility of the affected parts to touch, pain, temperature, and electrical stimulus was unaltered; but, as in the previous case, the sclerous integument was found to conduct a galvanic current much better than the healthy skin around.

Except an attack of small-pox, the patient had suffered from no previous illness, and the most minute examination discovered no other disturbance of health than the scleroderma itself.

Case 3.—A strong and healthy man, aged twenty-seven, suffered for some years from varicose veins of the left leg. In the winter of 1873-4 he struck the skin of the same side, and a sore resulted which remained long unhealed. During the next twelve months the hair gradually fell off from that leg, and the skin became irritable, hard, and fixed. At the beginning of 1875, almost all the left leg, from the ankle upwards, and more than half the thigh (except where the varicose veins occupied the surface), showed the characteristic features of scleroderma [described, as in the previous cases, with wearisome minuteness and endless repetition], the only feature specially worthy of note being that in the thigh the affected surface was below the level of the sound. The inguinal glands were not swollen. The patient felt the whole thigh squeezed as if in a tight bandage, but suffered no pain; and normal sensibility over the affected region was retained, as in the preceding cases, with the same improved conductivity of the diseased skin. As in other cases, the partial immobility of the limb depended simply on the state of the integument, and the muscles underneath responded to electric or other stimuli as usual. There was nothing in the man's family history to throw light on the complaint; he was not syphilitic; and the only fact his doctor could elicit was that, in his trade of wine-bottler, he had opportunity of drinking more wine than other people, and it so happened that the wines he had to do with were of the strongest sorts.

This patient had not been treated at the time when

his case was published. The other two had been faradised and galvanised in hope of producing a more active circulation in the skin, by stimulating the muscles underneath, and irritating directly with the faradic brush. The continuous galvanic current was also applied to the neck as a means of acting on the cervical sympathetic. Warm baths were prescribed, and Fowler's solution was taken internally. Slight improvement took place in the hands of the second patient under this treatment, but the disease spread over her chest.

The authors call attention to the precedence of oedema in two of these cases and varix in the remaining one: and to the participation of nails and bones in the morbid condition in the second case, as in some related by 'French observers.'

These three cases are preceded by a reference to the previous literature of the subject in the chapter by Kaposi in Hebra's *Handbuch*, which treats of scleroderma. This has already appeared in vol. iii. of the Sydenham Society's translation, by Mr. Waren Tay, pp. 105, 106, and it may be useful to give here the additional cases mentioned in the present article. They are as follows:—

REPORTS OF FOREIGN SOCIETIES.

ACADEMY OF MEDICINE IN PARIS.

November 23. *Metric Ophthalmoscope*.—M. Giraud-Teulon presented an instrument, the metric ophthalmoscope, intended to determine the refraction of the eye. It was distinguished from the similar instruments of *Lehring*, *Cohn*, *Knapp*, &c., by the following peculiarities. 1. It was the first ophthalmoscope of this kind constructed according to the metric system. It contained, in a disc, a series of twenty convex glasses. Each of the glasses was equivalent to the preceding one, augmented by a half, which gave 0.50, 1, 1.50, 2, 2.50, &c. 2. By laying on these glasses an additional concave glass of 10.50 dioptics. The same series of contrary signs or negatives (concave glasses) was obtained. A single disc of very limited dimensions, on which moved a single additional glass, therefore gave a series of forty-one glasses (twenty convex and twenty-one concave), which made the single-disc refracting ophthalmoscope the most complete hitherto constructed. 3. The metric ophthalmoscope contained a series of glasses with intervals of regular refractions, whilst in the instruments used up to the present time it had been necessary, on account of the restricted number of the glasses, to have irregular and compulsorily arbitrary intervals.

Myopia.—The discussion on myopia was continued. M. Giraudeau maintained the modern theory of accommodation by the ciliary muscle. M. Jules Guérin would place no faith in it, until he had been shown the crystalline lens curved by the action of the ciliary muscle.

December 7. *Myopia*.—M. Guérin endeavoured to establish that myopia was but a permanent condition of the accommodation of the eye to the sight of near objects; that the accommodation of the eye to the different distances of the field of distinct vision, was a phenomenon in which the whole muscular system of the eye took part, and which resulted secondarily from the appropriation of all the parts of the ocular globe, modified by this system; that the doctrine of the change of the form of the crystalline lens was contradicted by all the circumstances, all the degrees, all the modifications of accommodation, of which it had maintained one part and suppressed many others; that the origin, the characteristics, and the treatment of myopia, showed that it was only a modification in form of strabismus, like the other visual anomalies, astigmatism, muscular asthenopia, amblyopia, etc.; all were produced by different habits, different degrees, different distribution of muscular retraction. M. Maurice Perrin accused M. Guérin of confounding adaptation with accommodation. The present theory of accommodation, as it had been formulated by Donders, rested on an unassailable foundation, and was beyond discussion. Myopia

was intimately connected with accommodation. There was deformity of the eye in myopia with atrophy round the optic nerve, of which one species was, in fact, produced by muscular retraction; and M. Guérin had the merit of having made myopia thoroughly known, and of curing it by myotomy; but he had committed the mistake of generalising from special and exceptional facts.

December 14. *Aconite*.—M. Oulmont read a paper on aconite, its preparations, and aconitine. Struck by the inequality in the action of the various preparations of aconite, and the dangers to which it might expose practitioners not well accustomed to handle so powerful a drug, M. Oulmont undertook a re-examination of the pharmaco-dynamic and therapeutic properties of this drug. From experiments on the human subject and on dogs, he drew the following conclusions. The action of aconite is variable, 1. according to the part of the plant employed; 2. according to whence the plant comes; 3. according to its preparation. It might be generally premised that the leaves, stalks, flowers, and seeds have an uncertain and almost nugatory action; that the roots contain the active principle, and that they differ according to their habitat. The garden aconite is less powerful than that of the Vosges and the Swiss mountains; therefore the alcoholic tinctures of flowers, stalks, etc., may be given to animals in doses of from 30 to 40 grammes ($7\frac{1}{2}$ to 10 drachms), and to the human subject up to 20 grammes (5 drachms) without appreciable effect. The alcoholic tincture should only be prescribed in small doses on account of the unequal character of its action, which is due to the presence of the vegetant water in the roots. Tinctures of aconite are weak preparations, those of the root being more so than those of the leaves or the stalk; both have an unequal and uncertain action. The extract of leaves of the French *codex*, administered in doses of from five to seven grammes, produces only very moderate physiological effects. The extract of the dried roots of the Vosges aconite is much stronger, its action is equal and uniform, it is easy to calculate the dose, and it is the preparation to which preference should be given. It may be administered in doses of from two to three centigrammes (0.03 and 0.045 grain) at the outset, and gradually to fifteen centigrammes, without fear of accidents. The aconite of Dauphiné, and the Swiss aconite in particular, are to be rejected on account of the violence of their action and the difficulty of apportioning the dose. Aconitine possesses a very powerful action, at the same time well defined and regular; but on account of its violent effects, and perhaps the yet ill-determined varieties of this alkaloid, it can only be administered with the greatest care. Aconitine exercises physiological and therapeutic effects in doses of a quarter of a milligramme. It may gradually be increased to a dose of one and even two milligrammes a day without any ill effects.

ACADEMY OF SCIENCES IN PARIS.

November 8. *Unipolar Electric Excitation*.—M. Chauveau presented a note on the comparison of the unipolar excitations of the same sign, positive or negative. This note was the sequel of that published in the report of the Paris Academy of Sciences (LONDON MEDICAL RECORD, No. 6, Dec. 5, 1875).

The results obtained were these: 1. In the case of regularly increasing unipolar excitations the action of the positive pole, measured by the size and the duration of the contractions, increases in a constant manner with the intensity of the current, while the muscle has not attained the maximum of effect which it can produce. The increase of this action of the positive pole is often regular, like the increase of the current itself. At other times the increase, at first very rapid, becomes less and less so in proportion as we get near to the maximum of the contraction of the muscles. 2. The action of the negative pole increases at first with the current, and thus attains more or less rapidly, sometimes at once, a value beyond which the increase becomes slow, even stops altogether, or even changes into a weakening; which, in certain conditions, not, it is true, altogether physiological, arrives at an almost complete neutralisation of the activity of the current. 3. These two propositions, deduced from the study of unipolar excitation on the frog, may also be applied to man and the mammalia with some modifications, which will be subsequently pointed out. 4. In the last-mentioned classes the study of the influence exercised over sensibility by unipolar excitations gives results, absolutely opposite to the preceding, so that the same constructions may represent these results, if the positive curve be taken for the negative, and *vice versa*. As a practical consequence, applicable to the medical employment of electricity, we see that there is but one means of manipulating the current of the pile with regularity; that is, to induce unipolar excitation with the positive pole to act on the motor nerves, and with the negative pole, if it be required, to call sensibility into action.

Electro-capillary Currents produced by Mineral Caustics.—A note on this subject was presented by M. Onimus. According to the writer, there would be reduction of the metallic caustics in the tissues, as in M. Becquerel's experiments; wherever the metallic salt comes into contact with a membrane there is a deposit of metal on one of the surfaces.

Influence of Acids on the Coagulation of the Blood.—In a note on this subject M. Oré said that, if it had been possible to introduce chloral directly into the blood, it was because it is perfectly soluble in water. There are other substances which only become soluble by acids or alcohol, and these bodies may induce coagulation of the blood, since they coagulate albumen. But M. Oré stated that in the living circulatory torrent this effect has not taken place.

The Function of Carbon Acid in the Phenomenon of Coagulation of the Blood.—A note on this subject by M. Glenard was read. MM. Mathieu and Urbain having considered the results formerly presented by the author as inadmissible, he replied by a new experiment which confirmed his opinion as to the innocuity of carbonic acid with reference to the coagulation of the blood.

Function of the Spleen.—A note by MM. Malassez and Picard on the function of the spleen was read. The authors had continued their experiments, but they had divided the nerves on one side of the spleen. The results obtained were the following. The paralysed side always gives blood richer in corpuscles than the other side. The tissue also of the spleen contains more corpuscles on the paralysed side. The same holds good of the blood contained in the liver. This increase of the corpuscles cannot be attributed to the concentration of the blood. After the para-

lysis has lasted two or three hours, much less iron is found in the paralysed side than in the other. We may therefore admit a new formation of blood-corpuscles in the spleen at the expense of the iron contained in it.

December 6. *Pernicious condition of the Blood of Healthy Horses killed by being Stunned or Asphyxiated.*—According to M. Signol the blood left in the body for at least sixteen hours becomes rapidly deadly, if doses of twenty-four drops of it be introduced into goats or sheep. Bacteria and agglutinated corpuscles similar to those found in the blood of animals affected with *charbon* were found, which proved that these signs are not characteristic of *charbon*.

REVIEWS.

Lectures and Essays on the Science and Practice of Surgery. By ROBERT McDONNELL, M.D., F.R.S., Surgeon to Dr. Steevens's Hospital, etc. Part II. The Physiology and Pathology of the Spinal Cord. Dublin, 1875.

The first part of these excellent lectures has not come under the present writer's notice, nor is it referred to in this publication, which indeed is a treatise complete in itself. It consists of three portions. The first of these is a lucid, careful, and critical summary of Brown-Séguard's discoveries and speculations as to the functions of the spinal cord, a task for which Dr. McDonnell is the better fitted, since, in addition to his high qualifications as a surgeon and physiologist, he assisted Dr. Brown-Séguard in preparing his experiments at Dublin, preserved the preparations resulting from those experiments, and repeated many of them. It will not, however, be necessary for us to dwell much on this first part of the work. Suffice it to say that it contains a most clear explanation of Brown-Séguard's doctrines, as opposed to Sir Charles Bell's and Longet's, to those of Schroeder van der Kolk, and others, and of the reasons which have led Dr. McDonnell to accept, along with most other physiologists, those which relate to the function of the central grey matter of the cord in transmitting sensitive impressions, to the decussation of the sensitive fibres near their point of contact with the cord, to the presence of vaso-motor fibres in the cord and their influence on secretion and nutrition, and to the explanation given by Brown-Séguard of the phenomena of the muscular sense and of muscular spasm; while, in common with most writers, Dr. McDonnell reserves his assent to the great physiologist's teaching in regard to the existence of separate nerves for various modes of sensation. The student who wishes to obtain a clear view of the present state of this department of physiology cannot have a more competent or intelligible guide than this little volume. The second portion is an attempt to found on analogy and on deductions from the phenomena of sensation, a new theory as to its intimate nature. He rejects the theory of Brown-Séguard, which assumes a great number of fibres of diverse kinds for the transmission of diverse modes of sensation, a theory which indeed is very difficult to reconcile even with probability. Thus Brown-Séguard, in a most imperfect classification of the various kinds of sensation, has been obliged already to assume eleven different sorts of nerve-fibres; and of course, the more kinds of sensations could be distinguished, the more kinds of nerve-fibres must be

invented or imagined. But it is really very difficult to persuade oneself even of the probability of the existence of different fibres for the reception of the phenomena of touch, tickling, and pain, to say nothing of Brown-Séguard's eight other classes; while, as to evidence of the real existence of such separate fibres there is, of course, none whatever. The separate nature of the fibres which appreciate touch and temperature has been inferred by Herbert Spencer, but from most insufficient data, as Dr. McDonnell shows. In fact, there is no anatomical evidence of any difference between fibres of the most various endowments, and much reason to think that the difference in the phenomena produced by their irritation depends not on themselves, but on the centre with which they are in contact. Our author's theory harmonises well with the facts hitherto observed, and deserves attention as an ingenious and plausible conjecture. It is, that the phenomena of sensation are excited by a kind of undulatory disturbance of the particles of nerve-matter, somewhat similar to the undulatory nature of light and heat, and that the differences in the sensations represent differences in the magnitude or velocity of such undulations or disturbances. Dr. McDonnell supports this view by a very ingenious analogy with certain phenomena of the undulations of heat observed by Professor Tyndall, and shows how it is reconcilable with the various facts of daily life; but, though an interesting and not an improbable speculation, this remains, of course, as yet a speculation only.

The third portion of the work is the one to which readers will probably turn with the greatest interest. It is headed 'Lectures on Physiology applied to Practice.' It commences with a forcible and well reasoned defence of the practice of experimental physiology, or vivisection, as it is now the fashion to call it, and of the moral character of those who practise it, from the charges of useless and deliberate cruelty which are now so freely made. The controversy has proceeded so far, and is now so nearly advanced to an authoritative solution by the medium of the Royal Commission, that it is quite unnecessary here to pronounce any opinion upon it; but we may be permitted to observe that in this, as in most controversies, both sides have pushed their arguments too far. It would be absurd, and would only show an utter ignorance of the history of physiology, to maintain that no useful discovery has ever been made by experiments on living animals; and a perusal of Dr. McDonnell's pages would be quite sufficient to refute such an idea. Nor does it seem more reasonable to charge indiscriminately all those who pursue the great object of human effort—knowledge—in this way with deliberate cruelty. Yet while we have experiments recorded in works of authority, in which animals of all kinds have been put to death by almost every form of privation and violence, and mutilated in almost every way compatible with the preservation of life, it does seem pardonable that those of the public who feel an affection for the lower animals, and who regard them as being equally with themselves creatures of 'the common Father, kind to all,' should demand, at least, authoritative information as to what is done in our schools of physiology, that they may judge how far it is consistent with law and morality, and whether it requires any legal regulation. We make these observations, trite and obvious as they may seem, because it appears to us too much the fashion in medical writings to treat the proceedings of the Society for

the Prevention of Cruelty to Animals, and the opponents of vivisection, as if they were a causeless insult on the profession, and a wanton attempt to impede the progress of research. For ourselves, on the contrary, we expect from the whole movement, and from the labours of the Commission, some enactment which shall be as successful in preventing any public scandal as the Anatomy Act was in the somewhat analogous case of dissection; and which, like that Act, will rather assist than impede the attainment of the objects of the practice which it regulates. At any rate, Dr. McDonnell's book may be useful to those who pursue the controversy, by showing them exactly the nature of the experiments which are used by those who lecture on experimental physiology, and the amount of suffering which they involve to the animals who are the subjects of them.

There are four lectures. The first treats of the influence of the nervous system over the heart and blood-vessels, and illustrates the existence and action of the vaso-motor nerve, by the following experiments: 1. Plunging the hand into ice-cold water, and showing that the opposite hand is cooled to a very great degree, while the heat of the mouth undergoes no change; 2. The division of the cervical sympathetic in a living rabbit, showing the immediate occurrence of vascularity of the conjunctiva, vascularity and heat of the ear, and constriction of the pupil on the side of the injury; 3. The results of the same experiment performed on another rabbit some days previously, showing the persistence of the same effects, and the increased secretion of the lachrymal gland [the results of galvanisation of the sympathetic are related, but not demonstrated]; 4. The effects of galvanisation of the pneumogastric on the motions of the heart are demonstrated on a rabbit just killed with prussic acid and kept under artificial respiration, and the operation clearly and carefully described. The second lecture treats of the reflex phenomena of disease, explained through the influence of the nerves over the blood-vessels. In this lecture some of the previous experiments are referred to, and Pflüger's and Bernard's experiments are recited, and cases related, but no new experiments are exhibited to the class. The third lecture treats of the functions of the spinal cord and medulla oblongata; and here not only are Brown-Séguard's experiments referred to, but some animals are exhibited in whom similar sections had been made, in order that the phenomena might be verified before the cords were dissected, and the precise extent of the lesion ascertained. The fourth lecture deals with three subjects. 1. The hyperæsthesia met with in the posterior limb of the same side after division of the lateral half of the spinal cord, Dr. McDonnell is disposed to refer, in part at least, to the inflammation of the nervous centre produced by the section. 2. The muscular sense, and the pains which accompany spasmodic muscular contraction, he explains, after Brown-Séguard, by a disturbance of the galvanic condition of the muscles, or rather of the nerves distributed to them, and in support of this he exhibits to the class some experiments, after Du Bois-Reymond, with 'rheoscopic' frogs' legs. 3. Finally, he speaks of the artificial production of epileptic convulsions, and exhibits two experiments to the class, one in which the lateral half of the spinal cord had been divided a month before in a guinea-pig, and where the right cornea had become opaque, and slight irritation of the skin of the cheek on the

same side produced a general epileptic convulsion; the second, in which rotatory convulsions were produced by irritation of the auditory nerve in a rabbit, near its origin, illustrating the vertigo produced by injection of cold water into the ear, and the convulsions which children suffer from irritation propagated from the ear. Both these experiments are, we believe, repeated from Brown-Séguard.

This is a summary of the experiments exhibited by Dr. McDonnell to his class; and it cannot be denied that some of them involved pain and other suffering to the animals experimented on, and that all of them had been performed before, so that they were undertaken not for the purpose of original research but for that of demonstration merely. And obviously, if it is once admitted that experiments on animals are justifiable for the purpose of original research, it will be found utterly impossible to forbid their repetition. That repetition may be either for the purpose of mere demonstration, or for that of testing the result obtained in the original experiment; and the two objects are so nearly allied that it would be impossible effectually to separate them. Thus in so simple an experiment as that of plunging one hand into ice-cold water, Dr. McDonnell has shown how entirely the phenomena were at first misinterpreted until more extended observation of the effects of repeated experiments had supplied the true interpretation. Much more is this the case with the results of experiments on deep-seated organs of complicated structure and relations. If the alleged results of such experiments were admitted without further investigation, every kind of error would creep into our physiological teaching, and the very object for which experiments are instituted would be frustrated. Nor is there any test so good as that which is furnished by public demonstration. Dr. McDonnell's volume is a proof of the importance of such experiments, and of their immediate bearing on the pathology and practice of medicine, whilst its lucid style and vigorous method render it intelligible to a reader of average capacity, even if ignorant of medical subjects.

T. HOLMES.

Beiträge zur Geschichte und Statistik der offenen und antiseptischen Wundbehandlung. Zwei Abhandlungen von DR. R. U. KROENLEIN, Assistarzt am Königl. Chirurg. Klinikum, und Privatdozent zu Berlin. Pp. 86. Berlin: Hirschwald, 1875.

Dr. Kroenlein, the author of a book on the open treatment of wounds (mentioned in the LONDON MEDICAL RECORD, 1874), gives in the first of the above-named papers the history of the treatment of wounds, which shows that the open treatment and Lister's antiseptic treatment are the modern methods deserving more than others the attention of the profession.

In the second paper he tries—what has not been attempted hitherto—to compare the practical results of both these methods, and confronts for that purpose the cases recently published by Professor Volkmann, of Halle, and Professor Thiersch, of Leipzig, which have been treated antiseptically, with those of a period of open treatment carried out some years ago by Professor Rose and by himself, in the hospital of Zürich.

Out of all cases he selects the amputations, compound fractures, amputations of the mamma, and the accidental diseases: pyæmia, septicæmia, and erysipelas. We make only a short extract from his

tables, and must refer to the original paper everybody who wants to go further into the details.

Amputations of	Antiseptic Method			Open Treatment		
	Total	Died	Per Cent.	Total	Died	Per Cent.
Thigh	18	10	55'5	28	10	35'7
Leg	13	2	15'3	11	2	18'1
Foot	18	5	27'7	15	3	20'0

	Total	Died	Total	Died
	13	5	22	3

Pyæmia and septicæmia have not been entirely avoided, but have not been much diminished, by both methods, while erysipelas was less occurrent during antiseptic treatment, but frequently observed on openly treated cases.

The time of healing, as well as the results respecting the function of the limb, is decidedly in favour of the antiseptic method, because it raises the number of cases of healing by first intention; but it is more expensive than the open treatment.

The modification of Thiersch, who applies, wherever possible, salicylic acid instead of the car-

bolic acid, is recommended, and attention is drawn to the caustic and sometimes intoxicating power of carbolic acid.

The author does not conceal that his comparison of both methods is yet far from being of general value, and definitive, as only some single series of cases were disposed of, and as, perhaps, the most brilliant results of the antiseptic method are to be found in other provinces of operative surgery than in those referred to. But his material did not furnish him the desirable number of cases of this kind. May others follow him to contribute to this important chapter.

P. SCHLIEP, M.D.

On the Prevention and Treatment of Scarlatina and other Infectious Diseases by the Internal Administration of Disinfectants. By DAVID J. BRAKENRIDGE, M.D., F.R.C.P.E., Assistant-Physician to the Royal Infirmary, Edinburgh. Edinburgh: MacLachlan and Stewart. 1875.

In this short pamphlet Dr. Brakenridge attempts to answer in the affirmative the question, whether or not any disinfecting influence can be brought to bear upon disease from within the body; or, in other words, to answer the question, can we disinfect living tissue?

He concludes, from the experiments of Professor Polli, of Milan, and Dr. Sansom, that 'if we can so disinfect the tissues of a living animal, that when it is put to death they will resist putrefaction, there is no reason why we should not hope to be able, by suitable means, to arrest or prevent a zymotic disease.'

Acting on this belief, Dr. Brakenridge, who had been in the habit of leaving scarlatina to itself, resolved to try disinfectant treatment. Of the various substances used for this purpose he chose the sulpho-carbolate of sodium, which he administered to adults in doses of from twenty to thirty grains every two hours. In this manner sixty cases were treated without a single death.

Of fifty cases treated in the Edinburgh Royal Infirmary Dr. Brakenridge says, 'Of these, not one failed to make a perfect recovery. Nineteen were males and thirty-one females. Their average age was 17'5 years. The average duration of the disease before treatment was commenced was 4'4 days. Dating from the outset of the disease, convalescence with normal temperature had commenced—in eighteen cases in six days; in eighteen cases in eight days; in five cases in ten days; in four cases in fourteen days; in two cases in seventeen days.

'In only three cases was recovery long delayed by sequelæ, and in these the sodium sulpho-carbolate treatment was commenced on the sixth, tenth, and fourteenth days of the fever respectively—too late to prevent the after-effects of the disease. In forty cases no complication interfered with the quick and quiet subsidence of the fever. Albuminuria was observed in five cases; in three of these it amounted merely to a passing trace; in the remaining two it was persistent, and accompanied with blood and renal casts. These two cases are included in the three above mentioned, in which the treatment was commenced late. Rheumatic pains, which were easily controlled, occurred in three cases. In three there was inflammatory swelling of the cervical glands, which in one strumous child resulted in abscess. In only two cases was any delirium noted: in one it was severe; in the other very mild. In forty-six cases the temperature and pulse fell steadily

after the treatment was put in force. In only four was any rise over the first recorded evening temperature noted; in all of these it was insignificant in amount, and of short duration. Only one case came under treatment on the first day of the disease; the eruption was coming out and was well marked. There was another case of scarlet fever in the same house. Treatment was at once commenced, and next day the eruption had disappeared, and the pulse and temperature was normal, and remained so. In another case, on the ninth day of the disease the medicine was suspended, the supply having run short. On the same evening, the temperature, which both on that morning and on the previous evening had been 100° , rose to 103° .

'The patients who are taken into the Royal Infirmary are for the most part adults. But that the disease does always run a mild course in such cases may be inferred from the fact, that of twenty-four patients admitted into the scarlet-fever wards of the infirmary during August, September, October, and November, 1874—the four months immediately preceding the commencement of the treatment by the sodium sulpho-carbolate—no fewer than six died.

'Up to this point, the results I have obtained by this method of treating scarlatina entirely support the favourable opinion which Dr. Sansom formed of it from his own experience. I have, however, ventured to go still further than, in so far as I am aware, any one who has used internal disinfectants has hitherto gone. So marked an influence did this remedy seem to exert on the actual disease, and so well was it tolerated in full doses, and for a considerable period, by all my patients, old and young, without exception, that I determined some time ago, whenever I met with the disease in my private practice, to give the sodium sulpho-carbolate to all individuals exposed to the infection who were not protected by a previous attack. For I argued, if by internal disinfectants we can destroy or inhibit fevergerms after they have multiplied indefinitely, and produced their pathological effects within the body, may we not reasonably hope that, by previously disinfecting the tissues of the body, the germs which first find their way into them will be much more easily destroyed or paralysed? I therefore hoped thus to be able either to modify or prevent attacks of infectious disease.

'To be able so to control the activity of the disease-germs on their entrance into the body, that the resulting attack should with certainty be rendered mild and safe, instead of severe and dangerous, and the patient thus be protected against a future attack, appeared to me the more desirable end to be aimed at. For to prevent the attack altogether, however desirable this might be at the time, would be to leave the individual still liable to the disease. The results which I have up till now actually obtained have exceeded my utmost anticipations, and require, I am fully aware, to be recorded and received with due caution.'

Dr. Brakenridge administered sulpho-carbolate for the above purpose in doses of from five to thirty grains, three times daily, to persons exposed to the poisons of scarlatina, diphtheria, and measles. It was given in this way with complete success to forty-five persons.

[The success here recorded is very marked, but it should be remembered that the patients were

mostly adults, in whom the disease, with exceptions, it is true, is usually of a mild kind. The mortality at twenty years of age would in ordinary times, probably, not exceed 2 per cent.; and it is quite conceivable that Dr. Brakenridge had to deal with an exceptionally mild epidemic. We should like to see the remedy tried on a large scale in a severe epidemic amongst children under five years of age, where the mortality ranges from 60 to 70 per cent. It is to be noted, also, that according to our author's own showing the disease was in no case arrested or shortened.—*Rep.*] ALEX. COLLIE, M.D.

The Anatomy of the Lymphatic System. Part II.

The Lung. By E. Klein, M.D., Assistant-Professor at the Laboratory of the Brown Institution, London. Illustrated by 6 double plates of 27 Figures. 8vo. pp. 80. London: Smith, Elder & Co.

Dr. Klein's able researches into the lymphatic system of the serous membranes, undertaken for the Medical Department of the Privy Council, have been followed up by investigations into the lymphatic system of the lung, the result of which now lies before us in the shape of a volume similar to the preceding one, and, like it, illustrated by numerous well-executed plates, the expenses of which have, as in the case of Part I., been defrayed by the Government Grant Committee of the Royal Society. It had been originally intended to discover the relation of the lung lymphatics to the process of tuberculosis; but, it being ascertained how imperfect was our knowledge of the normal anatomy of the organ, specimens of healthy lungs have been first subjected to minute examination.

The subject has been treated of under two sections; the first of which deals with the normal, and the second with the pathological conditions of the lungs. Of the first section the first three chapters are devoted to the so-called endothelium, the matrix, and the lymphatics of the pulmonary pleura, the last two to the lymphatics of the bronchi and lung tissue proper. Of the second section, the first chapter is concerned with the changes of the pulmonary pleura in acute and chronic inflammation; the second with the relations of the lymphatics of the lung to the process of artificial tuberculosis in guinea-pigs; and the last to the relation of the latter disease to acute miliary tuberculosis in man.

Like the costal pleura and other serous membranes, the pulmonary pleura is covered with a single layer of epithelial cells. Now the condition of these cells is different according as the lung is expanded in inspiration or collapsed in expiration, for, since the area of the pulmonary pleura is increased in the former act, the cells investing it will become flattened out like other epithelial cells, and are pale and transparent, while from the comparative collapse brought about by the latter act the cells appear polyhedral, or even columnar, and become in substance distinctly granular. The lung of the guinea-pig shows this best, as it contracts much more than that of other animals, which may be accounted for by its possession of a special muscular coat. It seems that the differences between the epithelium of the pulmonary pleura of the collapsed lungs and that of the costal pleura is precisely similar to that between the upper surface of the ovary and the surrounding peritoneum, as described by Waldeyer.

The matrix of the pulmonary pleura is similar in

structure to other serous membranes, consisting of a connective tissue containing elastic fibres and cellular elements, but it is more delicate and thin. It is best examined in the lungs of new-born children and of guinea-pigs. In a horizontal section of such a specimen, hardened in spirit and stained with haematoxylin, a far better reagent than carmine, bundles of connective tissue fibres will be seen, and in each of the interfascicular spaces lies a flattened nucleated cell. These spaces, which have a free intercommunication, correspond to the 'Saftkanal system' of other serous membranes (see Part I.) Just as there is a difference between the epithelium of the free surface of the lung in distension and in collapse, so does the arrangement of the fibres in the pleural muscular coat differ in expiration and inspiration, being widely separated during the latter, and closely approximated during the former act. The muscular fasciculi are further best developed in those parts of the lungs which participate most in the respiratory movement, e.g. on the mediastinal and on the anterior surface, being scanty on the posterior aspect. The muscular coat finally stands in a direct relation to lymphatic absorption from the pleural cavity; for, since the lymphatics of the lungs are in intimate relation with the meshes between the muscular coat, and as during inspiration the meshes are increased in area, a kind of pumping action will be established, and the meshes will fill themselves from the pleural cavity. As, however, in expiration the meshes become compressed, their contents will be squeezed into the lymphatics of the surface of the lung, which communicate with them. This action, which is similar to that of the lymphatic absorption through the diaphragm from the peritoneal cavity (*vide* Part I.), though not of marked effect under normal conditions, becomes under pathological conditions of great importance.

The lymphatic vessels of the pulmonary pleura are best developed and easiest studied in the lungs of dogs and of young children, and may even be followed under a lens in a fresh specimen. They may be easily filled with a solution of Brücke's Berlin blue by piercing one of the large trunks with the cannula, bent at a right angle near the tip, of a Pravaz's syringe, the lungs having been previously moderately distended by the forcing of air into one of the bronchi. To perform a similar operation upon the lungs of guinea-pigs is a very difficult task. Little need be said about the structure of these lymphatics, their wall being composed, as in other lymphatics, of a single layer of epithelial plates. Some end in blind saccular dilatations. The lymphatics have their origin in the subpleural alveoli (Sikorsky), and their trunks anastomosing enter the pleura, and, finding their way through the ligaments uniting the different lobes, finally reach the bronchial glands at the root of the lungs. There are also branches which arise in the deeper parts of the lung, and join the network of the subpleural lymphatics. These deep lymphatics are narrower in calibre, have no valves, and are lined by a different kind of epithelium. In the pleura of the lung of the guinea-pig there are also lymphatic lacunæ, which are in fact the spaces between the fasciculi of the subpleural muscular coat. Do stomata exist on the surface of the pulmonary pleura? Various observers, including Dr. Klein, have established the existence of stomata in the central tendon of the diaphragm, in the omentum and peritoneum, and in the *septum cisternæ lymphaticæ magnæ* of the frog, these being the orifices of the

perpendicular lymph-canals, lined by a special layer of epithelial cells; and Dybkowski has proved, both by experiment and by microscopic examination, the existence of stomata on the costal pleura. With regard to the pulmonary pleura, Dr. Klein believes that its lymphatic vessels are in free communication with the pleural cavity; in other words, that there are stomata amongst the endothelium on its free surface. He has figured (Plate I, Fig. 1) a surface view of the epithelium of the pulmonary pleura of a rabbit in a condition of pleuritis, brought about by the injection of putrid pus into its pleural cavity. Here are seen groups of germinating epithelial cells, and in the middle of each is an opening—a stoma—rendered very distinct by a plug of fibrinous material stained by nitrate of silver. The same means of communication between the pleural cavity and the intermuscular lymphatic spaces have also been seen by Dr. Klein in the lung of a healthy guinea-pig. With regard to the process of absorption by these channels, it is plain that the respiratory movement of the lung plays the most important part. On the expansion of the lung, in inspiration, the stomata on the surface will gape, and the intermuscular lymph-spaces (in the case of a guinea-pig) will be distended. Thus the lymphatic system will become filled with whatever material, able to pass through the stomata, happens to be in the pleural cavity. During expiration, the stomata, lymphatic spaces, and lymph-vessels proper being compressed, their contents will be forced into the efferent trunks. In the guinea-pig, the subpleural muscular stratum aids considerably the respiratory motion of the lung.

With regard to the lymphatic system of the bronchi, Sikorsky discovered in dogs and cats certain inter-epithelial structures on the bronchial mucous membrane, which readily take up the carmine from a watery solution of carminate of ammonia introduced into the air-passages—the epithelial cells remaining unstained—and communicate with fine canals, which perpendicularly penetrate the mucous membrane, and form by anastomosis an intricate network, chiefly in the submucous membrane, from which the lymphatic trunks take origin, and accompany the bronchi toward the root of the lung. The lymphatics, according to their position, may conveniently be classified as *peribronchial* or as *perivascular* lymphatics, according as they are situated in the adventitia or accompany the branches of the pulmonary artery.

Dr. Burdon Sanderson and the writer of this monograph have found on the walls of the bronchi in rabbits as well as guinea-pigs certain lymphatic ('perilymphangeal') follicles which are analogous in every respect to the lymph-follicles found in the tonsils, in the intestine, and in the cortical part of true lymphatic glands. The rootlets of the lymph-vessels belonging to the bronchial adventitia are, like the interfascicular lymph-spaces of other connective tissues, merely spaces between the bundles which constitute the matrix. In these spaces, further, are found the connective-tissue corpuscles which, as is generally admitted, are but the linings of the bundles which border the spaces. As then the lymph-canal system is in direct communication with the lymphatics of the bronchial adventitia, it follows of necessity also that the connective-tissue corpuscles are continuous with the epithelium of the lymphatic vessels. It is further a question whether the corpuscles in question are branched like the cells of the cornea, or whether, like so-called endothelial cells

they are unbranched cell-plates arranged in a continuous row, and connected by an intercellular substance appearing as lines between the cells. In the serous membranes, as stated in the first part of Dr. Klein's monograph, both forms exist; and the same appears to be the case in the bronchi, for in the loose tissue of the adventitia the interfascicular spaces are lined by connective-tissue corpuscles identical with epithelial cells, while in the denser structure of the mucous membrane these bodies have rather the shape of branched cells. At any rate, whether they be branched or not, it is clear that the corpuscles in question are continuous with the epithelium of the lymphatic vessels.

Apropos of the experiments of Sikorsky it was stated that carmine particles found their way between the epithelial cells of the bronchial mucous membrane into the lymphatic system of the bronchus. Amongst the ordinary epithelial cells of the bronchial mucous membrane, of the rabbit in particular, may be seen after careful manipulation by sections and teasing, certain nucleated cells apparently branched, which differ from epithelial cells proper in shape, in refractive power, in the character of their nucleus, and in their mode of staining on treatment with hæmatoxylin. As these interepithelial bodies are continuous with the subepithelial connective tissue, it might be suggested that they are, after all, epithelial cells in conjunction with connective-tissue corpuscles similar to those described by Huxley, Heidenhain, Billroth, and others. Such view, however, does not commend itself to Dr. Klein, who, on account of the striking morphological difference between epithelial cells proper and the bodies in question, holds that the conjunction of the latter with connective tissue corpuscles proves them to be interepithelial connective tissue cells. Next comes the question, what is their physiological value? These bodies obviously correspond to the pseudo-stomatous tissue of the serous membranes; in other words, to a tissue bringing the free surface into communication with the connective tissue cells of the mucous membrane. The spaces in which the pseudo-stomatous cells lie are, in fact, the canals of communication between the free surface and the interfascicular lymph-spaces, in which lie the connective tissue cells of the mucous membrane. Thus we see how, in the experiments of Sikorsky, pigment may penetrate between the epithelial cells into the lymph-spaces of the bronchial mucous membrane. It is an interesting fact that Mr. Watney has found analogous structural conditions in the mucous membrane of the alimentary canal, which are, it is believed, of importance for the due understanding of the normal process of absorption in the digestive tract.

The last chapter of those concerned with the normal anatomy of the pulmonary lymphatic system is devoted to the perivascular lymphatics of the proper lung-tissue. According to the discoveries of Sikorsky, there is in the walls of the alveoli a system of canaliculi and lacunæ which are, as it were, the rootlets from which the lymphatic trunks, accompanying the larger blood vessels, originate. These lymphatic trunks enter the root of the lung together with the veins. In the connective tissue surrounding the smaller (microscopically large) branches of the pulmonary artery, lymphatics may be seen under the guise of regular tubes or of irregular lacunæ. In the large arteries there are more of the former and fewer of the latter, while in the small arteries the reverse is the case. With regard to the muscu-

lar coat of the pulmonary artery branches of the guinea-pig, Dr. Klein has discovered, what has hitherto been overlooked, that it is not continuous, but is interrupted here and there by connective tissue. By the side of the arterial branches are lymphatic vessels which have no valves, and whose wall consists of sinuous endothelium. That which has been stated regarding the rootlets of the perivascular lymphatics, holds good also for those branches of the subpleural lymphatics which originate in the walls of the superficial alveoli. The relation between the interalveolar lymph-canalicular system and the alveolar cavities seems to be an indirect one, through what may be termed pseudo-stomatous canals, and not a direct one, as Sikovsky maintained.

To sum up, the radicles of the lymphatic system of the lungs have a threefold distribution, as follows.

1. Over the walls of the alveoli. This system is represented by irregular lacunæ and anastomosing canals, giving origin to lymphatic vessels having a special epithelial wall. These, as regards their position, according as it is superficial or deep, may be classed as *subpleural* or *perivascular* lymphatics.

2. Over the walls of the bronchi. This system consists, in the mucous membrane, of irregular lacunæ and anastomosing canals, in the more external parts, *i.e.* in the adventitia, of smaller or larger spaces. From these originate vessels having a special epithelial wall, and forming in the adventitia of the bronchi a net-work—the *peribronchial* lymphatics.

3. Over the pulmonary pleura. This is a system of interfascicular lacunæ communicating by a few canals. In the lung of the guinea-pig there are in addition certain *intermuscular lymph-spaces*. Both discharge into the subpleural lymphatics.

The subpleural lymphatics communicate directly with the pleural cavity by means of *stomata*. By means of *pseudo-stomata*, the radicles of both the perivascular and peribronchial lymphatics communicate indirectly with the alveolar cavities on the surface of the bronchial mucous membrane respectively.

The pathological condition of the pulmonary lymphatic system will be considered in the second part of the review.

J. C. GALTON.

Recherches expérimentales sur les Effets de l'Augmentation de la Pression atmosphérique. By J. C. T.

PRAVAZ, Docteur-ès-sciences, Directeur de l'Institut Orthopédique de Lyon.

Numerous papers have been published from time to time upon this subject, nearly all of which are confined either to an account of the results obtained from the therapeutic use of baths of compressed air, or to a description of the peculiar symptoms which frequently occur in miners from the sudden changes of atmospheric pressure they are obliged to undergo. The physiological effects which follow submersion in compressed air have received comparatively little attention; and the works of MM. Hervier and Saint-Lager, Vivenot, and Paul Bert are the only ones which are not wholly devoted to the practical branches of medicine or industry.

M. Pravaz, being placed under circumstances peculiarly favourable to the prosecution of such a study, attempts to elucidate the purely physiological results of compressed air-baths, as far as they influence the mechanism of circulation and respiration, and more especially the excretion of urea and carbonic acid, and calorification, which he considers

give a just estimate of the activity of the nutritive process.

The author made use of the apparatus which

M. C. Pravaz employed for therapeutic purposes, which consists of a large iron recipient into which the air can be pumped by a steam-engine. All the

No. I.—At Normal Pressure.

No. II.—At 19 Centimètres Pressure.

No. III.—At 38 Centimètres Pressure.

No. IV.—At 76 Centimètres Pressure.

No. V.—Some time after the Bath.

No. VI.—At Normal Pressure.

No. VII.—At a Pressure of 19 Centimètres of Mercury.

No. VIII.—At a Pressure of 38 Centimètres of Mercury.

experiments were carried out on himself, and the most vigorous precautions were taken to place him under identically the same conditions for each experiment.

The baths lasted three to four hours, and the pressure used varied from 16 to 76 centimètres of mercury. With regard to the circulation, the author

confirms the result obtained by Vivenot, namely, that the arterial tension is increased in direct proportion as the pressure is increased. This may be

well seen from [the accompanying sphygmographic tracings, for which we are indebted to the kindness of Dr. Pravaz.

No. IX.—At a Pressure of 76 Centimètres of Mercury.

No. X.—After Removal of the Pressure.

The upper line marks the rectal, lower the buccal, and the middle dark line indicates the mean temperature.

— — — = pulse, + + + = respiration.

Here it may be seen that the line of ascension diminishes in height and becomes slightly oblique, while in all the tracings taken in the compressed air the summit is flattened, and the dicrotism, which is

evident in the first two tracings, becomes less obvious as the pressure is increased. After a slight acceleration of the heart-beat which follows the entrance into the bath, the pulse gradually becomes

slow and weak, which condition continues for some time after the removal of the pressure, as may be seen in the last tracing.

With regard to the respiration, he concludes that the depth of the movements increases, and their rapidity diminishes up to a certain point, which varies according to the strength of the individual; having reached this limit, the amplitude of the respiratory movements diminishes and they become more rapid. Immediately after the pressure is removed the respiration becomes deeper and shorter. These various points may be seen at a glance in the traces taken with the anapnograph of MM. Bergeon and Kastus.

The last chapter, which is devoted to the nutritive phenomena, forms the most novel and important part of the investigation. The results in the main confirm those already obtained by Paul Bert on the lower animals, and only then at enormously high pressures. The amount of urea increased immediately after entering the bath, and became relatively less during the succeeding hours, remaining higher than normal. After leaving the bath the amount suddenly diminished. The increase was much more marked at the medium than very high pressures. The amount of carbonic acid evolved per volume of expired air also increased with the medium pressures; when the bath was prolonged the increase was less marked, and when a certain height was reached, the amount decreased in direct proportion to the pressure employed. With the temperature, too, there was a temporary period of elevation after the bath was entered; then followed a diminution, which gradually increased with the pressure and continued for some time after quitting the bath.

In comparing the relations which these modifications bear one to the other, it is seen at once that the activity of the molecular changes at first increases absolutely and then diminishes relatively, and subsequently decreases absolutely in proportion to the height of the pressure and the length of time one remains in the bath. The temporary augmentation is easily explained by the condition of 'hyper-oxhæmia' in which the individual finds himself in an atmosphere containing a greater amount per volume of oxygen than the medium he is in the habit of breathing. [Respiration?—*Rep.*] The diminution in the activity of the organic operations is more difficult to explain. The author believes that the vascular tension, being mechanically increased by the increased pressure, produces retardation of the heart-beat. He thus makes two factors, (1.) increased oxygen-supply per volume of air; and (2.) increased arterial tension, to combat one another in such a way that, for the first few minutes after entering the bath, the great amount of oxygen gets the upper hand and increases the nutritive activity; while under the influence of a more prolonged sojourn in the compressed air, the increased arterial tension retards the heart's action, and thus reduces the amount of nutritive interchange in the system.

The changes which take place upon leaving the compressed air seems to be more striking than any others, and it seems a pity the author does not pay them more attention. The investigation is of a purely scientific nature, but may aid in the more exact application of compressed air-baths, which in some places have become fashionable. It also shows how far from advantageous such a mode of treatment may prove in some cases.

Clinical and Physiological Researches on the Nervous System. No. I. On the Localisation of Movements in the Brain. By J. HUGHLINGS JACKSON, M.D., F.R.C.P., Physician to the London Hospital, etc. London: Churchill, 1875.

This reprint, from the *Lancet* of 1873, consists of only twenty-five pages, but it is preceded by a preface twice as long, and followed by a reprint of three cases of convulsions reported by Dr. Gowers. Dr. Hughlings Jackson promises similar reproductions of papers which have appeared in various periodicals on the following subjects: Tumours of the Brain and Optic Neuritis, Syphilitic Affections of the Nervous System, Affections of the Sight in Diseases of the Nervous System, and the Physiology and Pathology of Language.

All who are familiar with Dr. Hughlings Jackson's writings will be glad to have his admirable observations in a collected form; and, when so much that is valuable is offered us, it may seem ungracious to criticise the form in which it is presented. But it would perhaps be better if the succeeding essays were less literally reprinted. Some writings, like Watson's *Lectures* or Virchow's *Cellular Pathology*, might well be treated as the text on which to hang comments and corrections, introductions and appendices, just as the older physicians dealt with Hippocrates and Galen, or Coleridge with Archbishop Leighton. But while an author can keep the recension in his own hands, the better course would seem to be that which is usually followed, to combine his observations into a continuous exposition, adding such references as may seem necessary to secure his rights of priority. Again, with respect to his question of priority, we think our author is too scrupulous in assigning to each observer his share in contributing to general conclusions which have been too gradually reached to belong to any one in particular. In science, he discovers who proves, and a happy guess is of totally different value from a demonstration. Lamarck's theory of evolution was justly put aside by his contemporaries, though now it turns out to have been right in its main drift; and if some of Gall and Spurzheim's localisations should prove not absolutely wrong, it could not make 'Phrenology' less of an imposture than it was. After Marshall Hall's 'epoch-making' discovery of reflex action in the cord, it was inevitable that the principle should be extended, at least hypothetically, to the brain. What was, and still is wanted, is to ascertain by observation and experiment how far and under what conditions it takes place. So, with regard to convulsions, that, like all so-called 'morbid' functions, they are part of physiology, and may be studied as experiments made for us by disease, is a truism; the merit is with those who have so studied them.

The same scrupulosity is sometimes shown by Dr. Jackson in apologising for some of his most reasonable remarks as, 'at first glance, extravagant or grotesque.' He is perfectly free from the foolish ambition of shocking stupid people, and need not suppose that his readers will receive anything he writes with less than respectful attention. Moreover, if, as we hope, this important paper will reappear, with the others promised to succeed it, in an uniform and compact form, we venture to draw the writer's attention to one or two blemishes which are excusable in periodical literature, but are scarcely suited to what will, we feel sure, be a volume of classical

value. We refer to such phrases as 'a clotted mass of movements,' 'the mildest criticism,' 'development in a coarse brutal way of the functions of some parts of the brain,' 'the movements of the heart and respiration are less frequent, and the temperature is abased (soon after the seizure of course is meant).'

But when a critic is reduced to find fault with style, it is often the best proof of the excellence of the substance; and, lest our preface should be as long as Dr. Jackson's, we turn to the subject-matter of the essay.

The introduction is occupied by an interesting discussion on the relation between the sensori-motor 'substrata of mentation' and physical changes on the one hand, and states of consciousness on the other. It is one of the author's merits to have insisted on the presence of the motor element in this substratum. Memory of words has more to do with the tongue than with the ear, and giddiness is objectively a motor, not a sensory symptom; 'the sensation which attends it is a state of consciousness accompanying the outgoing current.' The double use of the word 'sensation' is partly to blame for the confusion between consciousness of afferent impressions and consciousness of phenomena generally. If we kept *sensation* to its objective meaning, excitement of an afferent nerve and ganglion-cell, and used *perception* to include the consciousness of sensations or of movements, this difficulty would be avoided. There follows a valuable explanation of the principle of compensation, by which each part of the grey matter of the cerebrum 'contains processes [organs] for movements of the whole of the body, so that destruction of much of the brain may lead to no symptoms, while yet the derangement of the same part may produce symptoms by its discharge.' With respect to localisation in the hemispheres, we note the following remarks.

'In most people the left side of the brain is the leading (motor) side, the side of the so-called will, and the right is the automatic (motor) side.'

'Movements of the two sides of the body are represented in each side of the brain;' but, while accepting Dr. Broadbent's hypothesis that the bilaterally acting muscles of the two sides are represented in each hemisphere, Dr. Jackson would add that all movements are represented to some extent in both, but the most volitional and specialised least; and, on the other hand, that the most automatic and bilaterally acting (e.g. intercostals) are not quite as fully represented in their own as in the opposite side of the brain.

'Destruction of no part of the cerebral hemisphere produces loss of sight. Discharge of parts (I think posterior parts chiefly) produces coloured vision. Tumour in it leads to changes in the optic nerve (optic neuritis), in consequence of which defect or loss of sight may or may not follow. Disease of the posterior lobe (right) produces defect of perception.' 'Facts seem to show that the fore-part of the brain serves in the motor aspect of the mind, and we may fairly speculate that the posterior part serves in the sensory.' 'I believe that all the muscles of the body are represented in the cerebellum, as all are in the cerebrum, but in different order.'

The important principle that 'the order of loss of movements, faculties, etc., is from the special and voluntary to the general and automatic,' is illustrated by the effect of destroying lesions (hemiplegia) and of discharging lesions (convulsions). This principle had not escaped the notice of Sir Charles Bell, from

whom an interesting quotation is made on the progressive paralysis of drunkenness. It receives interesting confirmation by the careful report by Dr. Gowers of three cases which form the appendix.

We can only hope that the present publication is but the forerunner of a more complete volume, which shall deal with the many points in cerebral physiology on which the author has thrown light.

A Guide to the Microscopical Examination of Drinking Water. By J. D. MACDONALD, M.D., F.R.S.A., Assistant Professor of Naval Hygiene, Army Medical School. J. and A. Churchill. 1875.

Dr. Macdonald's *Guide to the Microscopical Examination of Drinking Water* has been designed, he informs us in his preface, 'for the use of Officers of Health and Naval and Military Officers, who have to determine the nature of the suspended matter in water used for drinking.' It cannot be doubted that medical officers of health, and officers connected with public services and in charge of bodies of men, should be in every way competent to determine the sanitary import of suspended matters contained in potable waters. To medical officers of health we look to see that a wholesome and pure supply is provided; that is, so far as may be possible, for there is scarcely a river or stream that furnishes drinking water free from impurities; and, what is even more alarming, the means at command for separating even mineral and coarser particles which may affect health, are imperfect and not at all to be relied upon. It is fortunate, therefore, that from a large proportion of the living creatures, animal and vegetable, found in drinking water, we are unable to trace any special injury to health; their presence, however, is a matter of importance, as showing organic impurities, that serve as pabulum, and as indicating a source of putrescence, which further and closer observation may prove of deep sanitary significance. Whatever is effected in the elucidation of obscure points in the life-history of the lower forms of life, which there is reason for believing to be hurtful to health, will be brought about by an intelligent use of the microscope. The author of the work before us has made an attempt to assist in this useful work; and we propose to inquire what success has attended his attempt.

On turning over the pages of Dr. Macdonald's book, it will at once strike the reader that he relies more upon the skill of his pencil than the descriptive powers of his pen; he furnishes a number of figures of organism, with only a short commentary on their natural history, while the rest of the book deals with their classification, thereby assisting in their identification rather than that of linking together particular forms with special effects. One half the volume is occupied with lithographed plates, which, although possessing merit as specimens of pen-and-ink drawing, lack the truthfulness and finish of steel-plate engravings; the beauty and delicacy of structure in a large number of forms is therefore lost. Two only out of the twenty-four plates are devoted to the examination of specimens of drinking water, and in one we notice the author has fallen into the common error of assigning the exquisitely formed desmids and pretty pinnularia to 'stagnant and impure water.' On the contrary, they are inhabitants of the clearest and purest running streams; and although their ova may be carried by floods and heavy rains into stagnant pools and bog-water, they soon perish or drag on a miserable existence. Most unicellular

plants prefer good water; the confervaceæ and confervoid diatoms, however, do often flourish in impure and brackish waters, and to which some of the species communicate a most unpleasant odour; if taken into the stomach, they likewise give rise to diarrhoea or derangement of health.

From their imperfect representation, we with difficulty recognise the curious filamentous threads, oscillatoriæ, whose wriggling movements over the field of the microscope cause them to be mistaken for animals. Spirilla, the longer, and micrococci the shorter and broken up segments of oscillatoriæ, are objects of interest to officers of health, since they may be always found in sewage-communications and in bilge-water, and are decidedly prejudicial to health. No attempt has been made, however, to show the sanitary import of the innumerable organic matters, vegetable and animal, or to separate the noxious from the more innoxious contaminations; and we must express dissent from Dr. Macdonald's statement that 'decaying animal matter, as well as vegetable matter, may consist of materials *proper to fresh water or foreign to it.*' Every kind of decaying matter found in fresh water must be looked upon as foreign to it, and may be extremely prejudicial to health, when least expected. Too much space throughout has been devoted to matters of no importance in the microscopical examination of drinking water, as the classification of organic forms, etc., and too little to substances about which in a hygienic point of view officers of health would like to know more. We confess to some disappointment on finding the barest reference to improved methods of research, and the employment of immersion-lenses, as the bacteria and other smaller bodies, as well as the delicate flagellæ, can only be studied with the very highest powers of the modern microscope. We miss also the interesting observations, instituted by Mr. Heisch, for determining in a ready way, and by the aid of the microscope, the presence of sewage in drinking water. His method, which may prove useful to officers of health, simply consisted in adding a small portion of pure cane-sugar to the suspected sample of water, which is then maintained at a temperature of 60° or 70° Fahr., and in a place freely exposed to light. In a very short time the mixture becomes turbid, and crowded with fungus mycelium; subsequently butyric acid is formed, and finally bacteria appear. Observations of this kind, when repeated and confirmed, will prove of use in detecting sewage-pollution, and may lead to important practical results in determining the precise conditions under which germs are developed and become a source of danger. We look in vain also for anything like a classified arrangement of waters derived from various sources, or according to their relative value as potable waters, commencing, *e.g.*, with the chemical, and passing to the microscopical characteristics of a good drinking water, to that of rain-water, upland surface, or bog-water, surface-water from cultivated lands; polluted rain-water, shallow well-water or ground-water, ordinary spring-water, and artesian well-water. A carefully arranged series of observations properly classified would be exceedingly useful, and enable officers of health and others to compare notes and found reports upon the unwholesome character of the water of the district. Dr. Macdonald's book might have been made a fitting atlas and supplement to the recent 'Report of the Commissioners appointed to inquire into the Pollution of Rivers and Streams,'

upon which sources the country is obliged to depend for its supply of drinking water. We regret that we are unable to award our unqualified meed of praise to the labours of one known to be skilled in the use of the microscope, and a competent observer as well as a teacher of hygiene.

NEW INVENTION.

IMPROVEMENTS IN TRUSSES.

We have received the following communication from Messrs. Arnold and Sons, the well-known instrument manufacturers of West Smithfield:—

(To the Editor of the MEDICAL RECORD.)

SIR,—In your journal of last month's date, under the heading of 'New Inventions,' appears an improved truss with ball-and-socket joint, which allows the pad to be placed in any position. We beg to say that neither principle nor general construction of the truss referred to is new. The ball-and-socket principle, with screw adjustment to fix the pad at any angle, was patented on August 28, 1874, no. 2,947, and we purchased the patent right of the said inventor. At the Leeds Exhibition this year one of the trusses referred to has been exhibited by us. We likewise enclose the patent specification for your inspection, in which you will find the ball-and-socket principle, which can be fixed at any angle, is claimed by the inventor.

We much regret having to trespass on your valuable space, but can scarcely allow the truss to be called a new invention, the same having been anticipated at least fifteen months ago.—We remain, Sir, your obedient servants,

ARNOLD & SONS.

35 and 36 West Smithfield.

MISCELLANY.

MORTALITY OF HOSPITALS.—Mr. James Heywood, F.R.S., President of the Statistical Society, has given the sum of 20*l.* to be presented with the 'Howard Medal' in November next. The essays, as already announced, are to be sent in on or before June 30, 1876. The full title of the essay is, 'On the Mortality of Hospitals (General and Special) in the United Kingdom in times past and present.'

PHARMACEUTICAL CHEMISTS.—On Wednesday, December 15, at the Major Examination of the Pharmaceutical Society, Miss Isabella G. Clarke, having passed the examination satisfactorily, was admitted a pharmaceutical chemist. There are several ladies on the register as 'chemists and druggists,' but this is the first instance in Great Britain in which a lady has passed the Major Examination as a pharmaceutical chemist.

ADMISSION OF WOMEN TO MEDICAL DEGREES.—We have the best authority for stating that the Council of the Royal College of Surgeons of England have arrived at the very important decision to admit women to examination for the diploma of Licentiate in Midwifery of the College. This diploma entitles its holder, by Act of Parliament, to a place on the Medical Register and a legal status in the obstetric department of the medical profession. Thus a pacific solution has been arrived at, of a question which threatened to involve a long-continued controversy. Three ladies have, we understand, already applied for examination.

NIGHT MEDICAL SERVICE IN PARIS.—The night medical service long talked of for the city of Paris is now organised and in operation since January 1, in its eighty *quartiers*. A very large number of medical practitioners in each *quartier* have announced themselves as being ready to give the benefit of their nocturnal services to patients who may require them. The names and addresses are posted at the police stations. From October 1 to March 31, the night medical service will commence at 10 P.M. and terminate at 7 A.M. From April 1 to September 30, this service will not commence until 11 P.M. and will terminate at 6 A.M.

INSECTIVOROUS PLANTS.—At the ordinary monthly meeting of the Royal Microscopical Society on December 1, Professor Bennett directed attention to some peculiar bodies he found in *Drosera*, *Pinguicula*, and other insectivorous plants. These bodies are below the cuticle, and have a glandular aspect. They exhibit some cross markings, which give them a superficial resemblance to the external glands of *Coleus*, described and figured by Mr. Slack, but they are not, as those are, epidermic structures of the nature of glandular hairs. They have evidently a different function as well as a different position, and Mr. Bennett thinks it possible they are organs of digestion.

WHAT SAVAGES THINK OF TWINS.—In Africa, according to Dr. Robert Brown (*Races of Mankind*), the birth of twins is commonly regarded as an evil omen. No one, except the twins themselves and their nearest relatives, is allowed to enter the hut in which they first saw the light. The children are not allowed to play with other children, and even the utensils of the hut are not permitted to be used by anyone else. The mother is not allowed to talk to anyone not belonging to her own family. If the children both live to the end of the sixth year, it is supposed that Nature has accommodated herself to their existence, and they are thenceforth admitted to association with their fellows. Nor is this abomination of twin births restricted to Africa. In the Island of Bali, near Java, a woman who is so unfortunate as to bear twins is obliged, along with her husband, to live for a month at the sea-shore or among the tombs until she is purified. The Kahsias of Hindostan consider that to have twins assimilates the mother to the lower animals, and one of them is frequently put to death. An exactly similar belief prevails among some of the native tribes of Vancouver Island. Among the Ainos one of the twins is always killed; and in Arebo, in Guinea, both the twins and the mother are put to death.

CARNIVOROUS PLANTS.—'Pinguicula' writes to the *Times*:—'Within the past three or four years the subject of carnivorous plants has received a considerable amount of attention from men of science and others. It has been asserted that certain plants, such, for example, as the sundew (*Drosera rotundifolia*), capture, dissolve, digest, and absorb flies and insects which are placed upon or happen to touch specified portions of these plants. The insects and flies are, it is stated, devoured in this manner for the purpose of supplying the plants with food. The attention the subject has excited, and the surprise expressed by many persons, led several to suppose that the utilisation of insects as food by *Drosera* was a new discovery, and perhaps some readers of the *Times* may like to be disabused of the idea that it is so. I met the following passage in an edition of "Combe's Constitution of Man," printed in 1835, at page 88:—"Sec. 5. No. 6. Destructiveness is given, and man is constituted with a carnivorous stomach, and animals to be killed and eaten exist. . . . Not only has nature taught the spider to construct a web for the purpose of ensnaring flies, that it may devour them, and constituted beasts of prey with carnivorous teeth, but she has formed even plants, such as *Drosera*, to catch and kill flies and use them for food." The italics are my own. Combe probably copied from another writer, so in all probability the vagaries of carnivorous plants were known half a century ago, instead of the other day.'

A TALE OF AN OLD INJURY.—I close my report with the following rich case, that, from the fact of its being ordered to be spread on the minutes, has become the property of the profession at large. No set of men in the world can appreciate it better or enjoy it more, and I only need add, to quiet any misgivings as to its publicity, that no one laughs over it more heartily than the M.D. who figures therein. Dr. — is one of our oldest practitioners. M. G. is a worthy old farmer of the Celtic race. The latter came into the doctor's office with his arm hanging down and a look of pain on his face. The doctor was going out, but stopped with a 'What is the matter, M.?' 'Shure, sur, I fell on the barn flure and hurt me arm.' 'You did, eh; well, off with that coat and shirt.' Off came the articles, and after a moment's examination the doctor exclaimed, 'Why, man, your shoulder is out.' 'Well! doctor, and can ye fix it?' 'Oh, yes; lie down on that lounge.' Before he complied he said a few prayers, and took a drink of whisky. Without more ado he was put through all the manipulations known to ancient or modern surgery, with no good result. The patient became exhausted, cross, and discouraged. The doctor, perplexed, his shirt soaked with perspiration, sat glowering at Mike in despair, when a thought struck him, and he asked, 'Mike, when did you do this—get the shoulder out, I

mean?' 'Shure, sur, I think it was about twenty-two years ago, in Ireland.' The two men put on their coats in short order, and one now never attempts to reduce a dislocation without asking WHEN. The other thinks it all right, but a mighty uncomfortable way of arriving at a conclusion. The fall on the barn floor that morning caused the supposition that then the dislocation took place, and it is readily seen how easy it was to fall into the error.—Dr. S. S. Towler, in report of Butler County Medical Society (*Transactions of Medical Society of State of Pennsylvania*, vol. x.).

INTERMARRIAGE AS A CORRECTIVE OF HEREDITARY TENDENCIES.—A review of the reports of the Perkins and Massachusetts Institutions for the blind, published in the *Edinburgh Medical Journal* for October contains some remarks on a point of great importance. They, as well as the whole report, which is stated to be of extreme interest, are from the pen of Dr. Howe, the author of a well-known work upon the *Causes of Idiocy*, and the trainer of Laura Bridgman and Oliver Casswell, who were blind and deaf from infancy. Referring to the question of enforced celibacy in certain cases, Dr. Howe writes: 'I formerly believed and taught that those persons strongly marked by scrofula, by tendency to insanity, by organic defects, as blindness and mutism, should crucify themselves, and abstain from marriage. Reflection and experience, however, have changed that opinion. I have known heroic instances of such martyrdom. But martyrdom is not a natural remedy for evil; and if it were, not one in ten thousand will resort to it. We cannot disappoint and thwart our natural instincts with impunity, even that good may come from so doing. The natural compensations for endurance of evils, and the natural remedies for such evils, are many and marvellous. The fact to be considered here is the strong tendency to perpetuation of defects and infirmities in offspring; but the remedy is not, ordinarily, an attempt to starve instincts which cry continually for gratification; nor abstinence from those parental relations which are essential for the highest development of the best part of our nature; because a more merciful remedy is provided by our Maker, in that strong power of recuperation from any morbid condition, not necessarily mortal, which pervades all organised beings, and acts as steadily as gravitation itself. Not self-crucifixion, but suitable intermarriage, will, in a few generations, counteract the tendency to perpetuation among the offspring of inherited infirmities and inherited vices.'

CRANIOMETRY.—The *Bulletins de la Société d'Anthropologie de Paris* (fascicules 2, 3, 1875) contain a very interesting and important paper by M. Broca, being a résumé of the 'Cranimetrical Instructions' which he had been commissioned to draw up for the guidance of anthropologists by the Society. In accordance with the directions of the Commission, these instructions are preceded by a description of the anatomy of the head, in which an entirely new anatomical nomenclature has been adopted, for which M. Broca craved the approval of his confrères on the ground of the obscure terminology hitherto in use in craniology. Among a number of novel terms may be instanced such words as endocranium and exocranium; pteron and discus for the ascending and the horizontal parts of the greater ala; inion for the external protuberance of the occipital; and basion, opisthion, staphanion, pterion for distinctive portions of the occipital, frontal, and temporal fossæ. M. Broca announces that this new system of cranial terminology will be soon published *in extenso* in the *Mémoires* of the Society. The same publication also contains a description of a negro skull belonging to the Anthropological Museum, in order to show how the normal parietal foramina may present such unusually large dimensions as to assume after death the appearance of artificially produced parietal perforations. At a previous meeting of the Society, on March 18, M. Broca had exhibited a skull taken by M. de Palmas from an ancient cemetery in the

Canary Islands, which presented a double parietal opening. In connection with the subject of arrest of development in the osseous and other parts of the brain, as shown by M. Broca in the paper on parietal perforations, he drew attention to the extraordinary spread of religious mania in France, of which he gave numerous instances amongst the higher as well as lower classes, and appealed to medical and other scientific men to devote themselves to the elucidation of this important subject.

INTERNATIONAL MEDICAL CONGRESS.—The Medical Societies of Philadelphia have taken the initiatory steps for the formation of an International Medical Congress, by the appointment of delegates from their respective bodies, who were empowered to organise and perfect a scheme for celebrating the centenary of American independence. In accordance with the authority thus given, the delegation has organised the Centennial Medical Commission, with the following officers:—President, Samuel D. Gross, M.D., LL.D., D.C.L., Oxon. Vice-Presidents—W. S. W. Ruschenberger, M.D., U.S.N., Alfred Stille, M.D. Recording Secretary—William B. Atkinson, M.D. American Corresponding Secretaries—Daniel G. Brinton, M.D., William Goodell, M.D. Foreign Corresponding Secretaries—Richard J. Dunglison, M.D., R. M. Bertolet, M.D. Treasurer—Caspar Wisper, M.D. Arrangements have been made for the holding of the Congress in the city of Philadelphia, to begin on September 4, and to terminate on September 9, 1876. The Commission propose the following general plan for the organisation and business of the Congress:—I. The Congress shall consist of delegates, American and foreign, the former representing the American Medical Association and the State and Territorial Medical Societies of the Union; the latter the principal medical societies of other countries. II. The officers shall consist of a President, ten Vice-Presidents, four Secretaries, a Treasurer, and a Committee of Publication, to be elected by the Congress at its first session, on the report of a Committee of Nomination. III. The morning sessions of the Congress shall be devoted to general business and the reading of discourses; the afternoons to the meetings of the sections, of which there shall be nine, viz.:—1. Medicine, (including Pathology, Pathological Anatomy, and Therapeutics. 2. Biology, including Anatomy, Histology, Physiology, and Microscopy. 3. Surgery. 4. Dermatology and Syphilology. 5. Obstetrics and Diseases of Women and Children. 6. Chemistry, Toxicology, and Medical Jurisprudence. 7. Sanitary Science, including Hygiene and Medical Statistics. 8. Ophthalmology and Otolary. 9. Mental Diseases. IV. The language of the Congress shall be the English, but not to the exclusion of any other language in which members may be able to express themselves more fluently. Gentlemen intending to make communications upon scientific subjects will please notify the Commission at the earliest practicable date, in order that places may be assigned them on the programme. In order to impart to the Congress a thoroughly international character, invitations to send delegates will be extended to all the prominent medical societies in Europe, Mexico, the British Dominions, Central and South America, the Sandwich Islands, the East and West Indies, Australia, China, and Japan. Invitations will also be tendered to medical gentlemen of high scientific position; and distinguished visitors may be admitted to membership by a vote of the Congress. There is every reason to believe that there will be ample hotel accommodation for all strangers visiting Philadelphia in 1876. Further information may be obtained by addressing the Corresponding Secretaries, Richard J. Dunglison, 874 N. 16th Street, and R. M. Bertolet, 113 S. Broad Street, Philadelphia.

THE SKULL OF MOZART.—A Vienna paper states that Mozart's skull is in the possession of Professor Hyrtl, who has preserved it, upon a silver embroidered satin cushion, beneath a glass globe. He has kept it as he would keep a sacred relic, and until recently, in order to avoid crowds of curious visitors, he had never shown this—his rarest trea-

sure—to anyone. The last resting-place of Mozart has never yet been definitely determined, and it is doubtful if it ever can be determined. It sounds rather strange to say that Mozart's last resting-place is unknown and yet his skull is someone's possession. Professor Hyrtl, according to his own story, came into possession of this most highly interesting relic in the following way:—He inherited the skull from his brother, and the latter had obtained it from a gravedigger at St. Marx Cemetery. In the year 1830 Hyrtl's parents died in Vienna and were buried at St. Marx's Cemetery. Their son, a brother of the Professor, an engraver by trade, had always loved his parents very tenderly and was accustomed to visit their graves frequently, and usually at an hour when the cemetery was deserted. This circumstance was noticed by the gravedigger of the cemetery, and occasioned him considerable surprise. He ingratiated himself into the good graces of the pious young man, and they became warm friends. The friendship lasted many years, until finally the gravedigger one day became very sick, and his young friend Hyrtl, the engraver, came to see him. The gravedigger, feeling that the end of his life was fast approaching, related the following story to Hyrtl:—He was once present, when a boy—many, many years ago—at a mass sung at St. Stephan's Cathedral which was composed by a certain man, Mozart. The music affected him so much that tears came in his eyes and the name Mozart was inscribed indelibly in his memory. Again many years passed by, when one day a very modest funeral took place at St. Marx Cemetery. The name of the person buried was Wolfgang Mozart, and he was a composer of music. They placed the coffin in a common grave, covered it with earth—at which proceeding the gravedigger assisted; but few persons visited the grave in the next few years, and later no one at all visited it, or troubled themselves about the distinguished dead. But he, the gravedigger, upon whom the music in St. Stephan's Cathedral had made such a deep impression, after many years, when the bodies were exhumed, went to the grave and took from the coffin (in which lay the last remains of Mozart) the skull of that distinguished composer, and this skull he had preserved until that moment as a most sacred relic. This skull he wished to make a present of to his young friend Hyrtl, the engraver, that he also might preserve it and keep it sacred till his death. Between the two men no conversation took place in reference to the situation of the common grave, but Hyrtl, the anatomist, who inherited the skull from his brother, says that the form and shape of the skull correspond fully with the bust of Mozart's head. Hyrtl also possesses documents in reference to this point, and vouches for the authenticity of the skull. Professor Hyrtl thinks he will, at some future day, present this invaluable relic to the Mozarteum at Salzburg. In the meantime it is to him a treasure of inexpressible value.

THE EARLY DAYS OF THE ROYAL SOCIETY.—The following interesting account of the early searches after knowledge by the Royal Society is taken from an admirable article in the *Builder* of January 8, 1876, entitled—“Some old Houses and their Stories.” After describing the foundation of the Royal Society and its first local habitation, the writer proceeds: “But really it does appear funny to see these grave, sober, stately philosophers desperately puzzled by Prince Rupert's drops, sent to them for investigation by their royal patron, the King, having been purchased, as it seems, in Rosemary Lane, and appointing a special committee of investigation to visit the glass house at Woolwich, and there experimentalise with them. It certainly is amusing to see them with a little kitten in their midst breathlessly anxious as they pricked it with a poisoned East Indian dagger, also sent by the King, which had previously been carefully warmed, and was expected to produce immediate death. But the victim's death was vainly watched for, and when the meeting broke up the poor little animal was still alive, and so remained. It is amusing, too, when we note the patient care and earnestness with which, at great trouble and expense, they

pursued their credulous inquiries concerning the wood that attracted fishes, and the fish that always turned to the quarter whence the wind was coming when suspended by a thread; as to whether snow-flakes were, as reported, larger in some countries than they are in others, and whether young vipers could be produced from the liver and lungs of old vipers, ground into a powder; as to whether the corn rained down from heaven at Norwich would, if planted, grow, and as to the nature of the white powder which at once made cold water hot. Nor is it, with the light we have from the candle they lighted, remember, less curious to see them, full of child-like wonder, performing their experiments with the horn they believed to be that of the unicorn, setting a spider in the middle of a circle of powder made therefrom, anxiously watching it, and very much puzzled by its contemptuous disregard of their efforts to confine it within that supposed mysteriously wonderful circle. Again and again was the spider caught and put back within the magic powder. Again and again did the long-legged insect straddle indifferently over it and hurry away. But once—the eagerly bent-forward heads of the philosophers noted it with a sudden start—once the spider while in the midst of the powder actually paused! Imagine how they held their breath amidst profound stillness, while every distended eye was full of startled expectation. But nothing wonderful came of it. The spider, having made up its mind which way to go, pursued its scrambling way as before. It was only a little uncertainty on its part—nothing more. They write to one of their foreign correspondents—one Sir Philiberto Vernelli, “resident in Batavia in Java and Major”—requesting him to ascertain “whether diamonds and other precious stones grow again after three or four years in the same places where they have been digged out;” and “What river is that in Java that turns wood to stone?” and again, “Whether in the island of Sumbero, which lieth northward of Sumatra about eight degrees northern latitude, there be found such a vegetable as Mr. James Lancaster relates to have seen, which grows up to a tree, shrinks down, when one offers to pluck it up, into the ground, and would quite shrink (down) unless held very hard? And whether the same, being forcibly plucked up, hath a worm for its root, diminishing more and more according as the tree groweth in greatness; and, as soon as the worm is wholly turned into the tree, rooting in the ground, and so growing great? And whether the same, plucked up young, turns up by the time it is dry into a hard stone much like to white coral?” Things quite as extraordinary crop up in old minutes of the Society, wherein we read of “Burning-glasses made of ice,” of “snake-stones and other antidotes,” of frozen swallows taken from under the ice of rivers and restored to life, of birds in shells adhering to trees in multitudes. The spirit of simple earnestness and humility so clearly visible in these early inquiries into things most incredible and strange crops up also in the first Catalogue of the Society's Museum, which was first established in Gresham College, Bishopsgate, wherein we are told how, on certain occasions, the porcupine shoots out its quills at pursuing enemies; how certain squirrels cross rivers by the aid of bark from a tree, and erect their tails to serve as sails; how elephants go mad in winter when it begins to rain, “and so continue from April to September chained to some tree, and then become tame again;” how unfortunate “tortoises, when turned on their backs, will sometimes fetch deep sighs, and shed abundance of tears;” how the feathers of the humming-bird are “set in gold, and sell at a great rate,” and of “a mountain-cabbage one reported, 300ft. high.” And for the collection itself the same credulity accepted everything, the absurdity of which had not been fairly demonstrated. Thus we find amongst other similar wonders, it contained “a bone, said to be taken out of a mermaid's head,” “a stag-beetle, whose horns wove in a ring are good against the cramp,” “a siphatter, said with its sucker to fasten on a ship and stop it under sail,” and “the white shark, which sometimes swallows men whole.”

The London Medical Record.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

BEAUREGARD ON IDIOPATHIC SALIVATION.

La France Médicale of July 14 and 17, 1875 (nos. 56 and 57), contains an article by M. Beauregard giving details of two cases of idiopathic salivation. He was induced to publish them by the report in the same journal for March 13 last of a case read to the Société de Médecine pratique de Paris. This case occurred in an old lady, who had long suffered from indigestion. After a great trouble had befallen her, she found her pillow soaked with saliva. The secretion always occurred at night, and amounted to at least a pint. Medical treatment appeared entirely without effect. The general health of the patient did not seem to suffer, notwithstanding this profuse discharge. M. Beauregard remarks that idiopathic cases of ptyalism become rare in proportion to the advance of our knowledge. By idiopathic is meant cases in which no cause is discoverable. Singular cases of salivation have been handed down to us from very remote times. Not to mention the remark of Hippocrates on laryngeal phthisis,* there were during the seventeenth century a large number of theses, memoirs, and observations, which have been carefully collected by Franck (*Pathologie Médicale*, tome v. obs. ii. 1842). In more modern times Portal, Sydenham, Morgagni, Franck, Tanquerel des Planches, Donne, Lhéritier, Denis, Golding Bird, Simon, Wright, and Landerer have all recorded rare cases. Very lately M. Dujardin-Beaumetz gave two excellent clinical lectures on this subject at the Hôtel-Dieu [published by M. Campenon in the *Gazette des Hôpitaux*, 1872, pp. 111 et 117.] Thus from time to time new sources of salivation have been discovered, and it may not be uninteresting to enumerate the chief causes now recognised as giving rise to ptyalism. This symptom is never absent in the various forms of stomatitis, especially at a certain stage in the membranous form of ulcers of the mucous membrane; in glossitis, aphthæ, and during dentition; after the use of certain mineral poisons, salts of mercury, of bromine, iodine, gold, etc.; or of certain sialogogues, such as pyrethrum (pellitory of Spain), and pimpinella saxifraga, vinegar, pimento, betel-nut, some zymotic poisons, as variola, malarious fevers; and lastly cadaveric and morbid emanations. Gubler remarks that some students are not able to dissect a single hour without being attacked with salivation of a distressing kind. This group, comprising the commoner forms of salivation, has been called by Spring, *Ptyalism from direct irritation*. There is, however, a group of cases, no less dependent upon irritation, and just as truly reflex, but caused by sympathy with remote organs, the salivary

glands and their ducts not being primarily affected. The greater number of these must be attributed to the stomach. This is perhaps not wonderful, when we remember Dr. Beaumont's experiments on Alexis St. Martin, and the more recent ones of M. Maillot, on a man whose œsophagus had been divided. He observed that every time that food was put into the stomach by the lower end of the œsophagus, saliva could be seen running from the upper and divided portion. An abundant flow of saliva is one of the first effects of hunger. In a great number of the diseases of the stomach, spontaneous, and often intractable, salivation is one of the symptoms. It is so in the indigestions, in cancers, perforating ulcers, etc., and in tapeworm also. It is also met with in uterine and ovarian affections, especially in congestive states, such as pregnancy and catamenial periods. G. P. Franck, Keck, Rahn, Widiking, Portal, and others, assert the same for the liver and pancreas, especially when cancerous. This is, however, less certain.

Next to ptyalism from irritation, authors describe a *critical salivation*, such as one sees in the second week of typhoid fever, in confluent variola, certain forms of severe meningitis, in dysentery (Sydenham), and such as we sometimes endeavour to produce, in such cases, by the therapeutic use of mercury. 'Clinical observation has also established the existence of complementary salivation succeeding the suppression of the catamenia (Royer-Collard), or of habitual leucorrhœa (Tanquerel des Planches), and other analogous circumstances, such as the diminution or cessation of the urine or perspiration.*' Physiologists (as Bidder and Schmidt) have shown that the parotids, like the skin and kidneys, may serve as channels to eliminate the watery portions of the blood, and may thus be called upon to supplement deficiencies in this direction (Gubler). This will explain the singular cases recorded by Gimpert, Forestius, Rondelet, and Solander from the effects of cold, and by Franck in the course of chronic skin-diseases.

There is lastly a class of cases of ptyalism, which may be called *nervous*. Recent physiological works throw much light upon this. Moral emotions, anger, hysteria, epilepsy (Voisin), are often thus accompanied. Fr. Homann (*Diss. de Salivæ necess. Inspectione*) says that lypemaniacs and hypochondriacs are subject to salivation. 'Nihil frequentius occurrit in praxi, quam quod hypochondriaci, melancholici, quotidie salivam exspuunt largissimam.' The physiology of the lingual, glosso-pharyngeal, lesser petrosal, and chorda tympani nerves explains the salivation which accompanies their functional or organic lesions. [See the *Compendium de Médecine pratique* of Moneret and Fleury, for a case of facial neuralgia inducing salivation; and the *Gazette des Hôpitaux*, 1868, for excision of the lingual nerve by the medical missionary, Maggioni. Burgius, in *Miscell. Acad. Nat. Cur.*, section ii. an. ii. obs. 173 (p. 338), gives an example of chronic tinnitus aurium terminating in spontaneous salivation; and J. Power (*Medical Transactions*, vol. ii. p. 34) mentions a case of ptyalism induced by a tent of lint which had been left in the ear. These nerves are also affected in intracranial tumours.] But nervous ptyalism always coexists with disorders of some

* 'Et ubi sanguinem exspuere desierit, salivam multam liquidam exspuit, quandoque vero etiam viscosam.'—Hippocrates, *De interiorum affectuum causis liber*.

* Hunerwolff has seen gouty metastasis to the throat and soft palate followed by salivation. Hoffmann mentions periodical salivations supervening on an attack of gout. (*De Podagrâ retrocedente*, par. ii.)

other organs. Tanquerel des Planches says he does not know a single case of purely *hereditary* nervous or other salivation apart from some other disorder.

We thus see that the majority of cases of excessive flow of saliva can be referred to one of these four classes [*irritative, critical, complementary, or nervous*]. There are, however, cases the cause of which is very difficult to discover. The following is an example.

D., aged thirty, of light complexion, strongly built, a lattice-maker, having several very healthy brothers, had for ten days suffered from a singular salivation. His antecedents furnished no explanation. He smoked but very moderately. He was not a drunkard. The salivation came on suddenly; it was increased by exposure to the air. The quantity of saliva was excessive, compelling him to spit incessantly. At the beginning it was intermittent, and first one salivary gland, then another was attacked, which he knew by slight pains in the glands, and by variations in the quantity of the saliva. The mouth, carefully examined, appeared healthy. His digestion was good, he had no pains in the head, and his general health was excellent. This case would have justly been classed as idiopathic, had it not subsequently been discovered that the man had gonorrhœa. Bayle, in the *Nouvelle Bibliothèque Médicale* for 1828, mentions a case of spontaneous salivation in a man of sanguine temperament and good constitution, aged thirty years, simultaneously with a slight gonorrhœa. He had never had any venereal disease, nor used any mercury. The saliva was normal, and the mouth healthy. After a few days of mild treatment the gonorrhœa disappeared, and the pytalism persisted. These cases may then be referred to the class of irritation from sympathy.

There are other cases where the causes seem multiple and complex, as in this case, occurring in the practice of M. Beauregard senior, at Havre. M. V., a captain in the merchant service, who had retired for some years, aged forty, of healthy and vigorous constitution, had had from infancy a tendency to squamous and scabby eruptions. His mother had also suffered many years from eczema of the scalp. He had also suffered from syphilis, which had left no permanent marks. In spite of voyages to the tropics, his health was good till nearly forty, when he was attacked in Calcutta with something like cholera [*dysentery.—Rep.*] which lasted six months. Since then he had several times suffered from severe diseases of the digestive organs, as about 1860 he had eighteen months of severe gastritis. In 1863 he suffered a relapse, with œdema of the legs. All this passed off, leaving him dyspeptic, with anæmia, and a tendency to syncope, to vomiting, and to headaches. For three years past his salivary secretion had been excessive. It was, however, only for one year that he had suffered from the singular salivation about to be described. Towards March he was called to Metz, and visited the battle-field of Gravelotte. It was a severe season; he took cold, and towards the end of a meal was attacked with facial paralysis, which soon disappeared, leaving behind it a profuse pytalism. Two months afterwards he was attacked with severe membranous and ulcerative stomatitis. The soft palate, gums, and inside of the cheeks were covered with thick white membranes. The tongue was greatly swollen and painful. Though obstinate, this yielded to chlorate of potash and alum gargles, etc. Now he has psoriasis

of the scalp and nails, is much emaciated, and often faints. He also suffers from heaviness, tendency to sleep, and slight giddiness on rising in the morning. His sight is feeble; there is some amaurosis, and the field of vision is circumscribed. He cannot distinguish some colours. There are pains in the loins, and his hands are somewhat tremulous. On stormy days, he sometimes experiences very severe and painful shocks. He does not define the exact seat of the pain. Ophthalmoscopic examination did not reveal anything special. Yet in the left eye an object required to be placed on his cheek to be seen. The Daltonism is intermittent. Examination of the heart, lungs, liver, spleen, and kidneys disclose no marked physical signs of disease. The belly is rather tympanic. There is tenderness on pressure in the epigastrium. The mucous membrane of the mouth is rather pale. No lesion is discoverable in the salivary glands. The sublingual glands are a little swollen in the early morning before he expectorates. There are slight fissures on the tongue. After the attacks of syncope and vomiting, his pulse intermits every fourth beat. He spits from four to seven pounds of saliva daily. Stormy weather and chalybeates increase the flow. After bilious vomiting it is lessened for some hours; this happens frequently now. Milk and Vichy water render the saliva less tenacious. Liquids, especially water, transform the secretion into a viscid mass, easily swallowed. Solid food is rendered disgusting by it, on account of its glutinous nature. There is neither sugar nor albumen in the urine. That passed at night is pale, copious, slightly turbid; the day-urine is scanty, red, and thick. The saliva has a specific gravity of 1.001 only, instead of 1.0088; it is notably alkaline, but contains neither sugar nor albumen. The secretion continues at night. He has often taken calomel as a purge. The stomach affection, cold, and mercury seem the chief factors in this case. As regards the effects of medicines, M. Tanquerel des Planches says, that in the twenty-nine cases in his work there were eight spontaneous cures, twelve appeared due to medicines, and in nine cases the complaint was persistent. Of remedies, opium has been most praised. Belladonna is now generally preferred. Astringents of various kinds, quinine, and even mercury, though it increases the flow at first, have all been recommended. Guimper cured one patient; but in Mitscherlich's case it failed, though conjoined with diet, for there was a relapse in three weeks. One method of treatment—the use of diuretics and diaphoretics—has not been tried as, perhaps, it should be. Jaborandi is now being used in the case of M. V. above given. It has temporarily increased the flow of saliva. The results of its employment are as yet uncertain, as it is still being given.

W. BATHURST WOODMAN.

HEUBNER ON SYPHILITIC DEGENERATION OF THE CEREBRAL ARTERIES.

THE most considerable addition to the literature of this subject is a monograph by Dr. Heubner, of Leipzig, one of the members of the Medical Faculty in the University of that city. Although his book was published last year, as it has not been circulated in this country and is not generally known here, we purpose giving a short account of it, more especially dwelling upon the anatomical descriptions.

Dr. Heubner commences by taking up the history of his subject, beginning with the writings of

Nicholaus Leonicens in 1497; he then passes to the recent history of the subject, and publishes forty-five cases which he has collected from the journals; to these he adds five cases of his own, with very full histories and *post mortem* examinations of the tissues both macroscopically and microscopically; these, in fact, form the material for his next chapter, which contains a very interesting account of his generalisations of the results of his observations in the previous cases. The following is a summary of his views.

First Stage: Anatomical Appearances.—An aggregation of small cells or nuclei is observed lying close under the normal lining layer of epithelium, and between it and the membrana fenestrata. These nuclei are closely packed together, but a little later on show between them a delicate stroma. The tumour presses forward the normal epithelium so as to encroach upon the lumen of the vessel, but at times the bulging is outwards so as to press upon the membrana fenestrata; he thinks this is due to variations in the blood-pressure depending upon the position of the artery, the direction of its axis, and the strength of the heart's systole. He believes the above-described nuclei or small cells to have originated by proliferation from the normal epithelium of the lining membrane. As this new formation goes on developing in size, round cells make their appearance in groups lying in the muscular and fibrous coats; these, he says, are wandering cells derived from the vasa vasorum, going to the tumour to nourish it; this process is necessitated by the weakening of the blood-supply. The tumour continues to grow, arranging itself round the lumen, narrowing it, but becoming itself compressed to form an excentric layer; complete obliteration of the lumen is long before it occurs, and thrombosis is rare on account of the gradual development of the obstruction. The morbid process grows in the long axis of the vessel, and passes into the smaller branches.

Second Stage: Organisation of the New Formation.—Little lumina make their appearance in the tumour; they are most numerous at its periphery. These are newly formed capillaries, and their direction is in the long axis of the original vessel; at first they probably contain only lymph, but afterwards blood. This vascularisation explains the absence of fatty degeneration; he has only seen an occasional granular cell, which was probably a wandering corpuscle. The next change is in that part of the tumour next the epithelium, which becomes more homogeneous, less cellular, and finally assumes the aspect of a membrane which Dr. Heubner believes to be the homologue of the original membrana fenestrata. Immediately internal to this, the cells have become spindle-shaped, and have arranged themselves circularly round the lumen of the vessel; beyond these again is another layer like embryonal connective tissue, but differing from that by the intercellular substance being fibrous, not jelly like; in fact, resembling the striped laminae of the aortic lining membrane. In these two layers the author sees homologous muscular and fibrous coats, and says the anatomical appearance is so exact that one can say a completely new arterial coat has been formed from the new formation. In speaking of this, he refers to the normal development of vessels from the epithelial coat of the embryonic capillaries, and to the observations of Billroth and Czerny on the formation of new vessels in plexiform sarcomata; he also refers to the formation of new bone after syphilitic periostitis as an analogous process.

Third Stage: Degeneration.—This is probably a later stage of the affection, but the second stage may be only partially completed, or never occur at all. The artery may be completely occluded by the nuclear proliferation; the cells disappear from the inner layers of the new formation, the interstitial tissue increases, shrinks, and drags in the original coats from all sides, crumpling and bending the membrana fenestrata; the lumen has quite disappeared, and in its stead, within the membrana fenestrata, lies a partly loose, partly dense bundle of connective tissue, sparingly supplied with capillaries. The cells of the muscular coat atrophy and disappear, and in place of the circular fibres there is only a network of elastic fibres enclosing detritus; at last even this becomes absorbed; the membrana fenestrata is no longer distinguishable from ordinary connective tissue, and in the place of the artery is left a slender fibrous thread, which is torn by the least manipulation.

He points out that this disease differs essentially from atheromatous degeneration, in its duration, anatomical appearances, and mode of termination. Atheromatous degeneration is essentially chronic, taking years, even decades, to become complete; while, on the contrary, this disease seems capable of producing extreme degeneration in one or two years. The anatomical appearances in atheroma are at first those of a true hypertrophy of the inner coat, for instance, that of the basilar artery becomes like the normal inner coat of the aorta. The calcification and fatty degeneration of atheromatous arteries are quite peculiar, and have nothing in common with the method by which syphilis destroys the vascular system. Lastly, atheroma attacks the greater and middle arteries, syphilis the middle and smaller ones; syphilis is, as far as his present observation goes, restricted to the arteries of the brain, atheroma attacks arteries in all parts. In speaking of the nature of the new formation in the syphilitic form of disease, he says that he does not know any reason for believing it a specific product, but considers it 'a quasi-inflammatory cell-proliferation of the epithelium, such as we find in the healing of wounds; but he believes that it is peculiar to vessels containing syphilitic blood, and thinks it probably due to the irritation of a specific syphilitic virus.

The next chapter is devoted to a description of certain anatomical investigations which Dr. Heubner was induced to undertake with the hope of throwing some light upon the physiological effect of this disease. These are some of his conclusions.

1. The six arteries rising from the circle of Willis have free communications with one another in the pia mater, and can thus supplement one another.

2. Each of the small branches, both anterior and posterior, going to supply the central ganglia, distributes itself in a definitely circumscribed area without anastomosing.

3. There are two sets of vessels given off from the primary divisions of the circle of Willis. The first, or central, are like the straight slender shoots that rise round the base of a forest tree and have few secondary branches; the second, or peripheral, form a vast ramifying mass like the head of the same tree. The central run through the perforated spots to the central ganglia and are terminal arteries; the peripheral ramify and inosculate in the pia mater and pierce the grey matter to supply the hemispheres. These facts enable him to arrive *à priori* at the

results of certain pathological conditions; for example, plugging of a peripheral artery would lead to temporary loss of consciousness, ending probably in recovery; plugging of a central artery, on the other hand, would lead to hæmorrhagic infarction or softening. He then considers the consequences of the arterial changes upon the brain-functions; he cannot say what effect the mere change from elastic to somewhat rigid tubes would have upon the blood-supply, but we may be sure the partial local obstructions and narrowing of the arteries in some places, and their complete obliteration in others, has great effect on the general vascular tension. Ludwig (*Die Physiologischen Leistungen des Blutdrucks*, Leipzig, 1865) has shown the dependence of the proper functional activity of the brain upon a proper degree of tension in the vessels. Besides, the retardation and diminution of the stream must cause defective nutrition and oxygenation, as well as probable retention of waste products in the lymph-spaces. He thinks that there is therefore sufficient physiological explanation for the loss of consciousness, delirium, and typhoid condition often noticed; he draws especial attention to this somnolent condition as being altogether something *sui generis*, and almost pathognomonic of the affection; he describes it as 'defective consciousness without entire loss of intelligence, the suppression of voluntary actions without the abolition of will impulses, the appearance of delusion and delirium varied by a sudden return to reason, a condition of half-sleeping, half-waking, half-dreaming.' The last chapter is devoted to a systematic description of the disease as it appears clinically. Under etiology, he places constitutional syphilis as the prime cause, thinks it is not affected by sex, that it is most common between thirty and forty years of age, and that there is some reason to believe in the influence of hereditary predispositions to diseases of the nervous system. The symptoms are (including the usual catalogue of nervous ailments) hemiplegia or apoplexy, loss of mental power, convulsions, contractions, the somnolent condition described above. Affections of single nerves are rare; aphasia is common; there are vomiting and fever during sudden attacks like convulsions, or preceding death. Its duration is difficult to define, from a few months to years. The diagnosis depends on the syphilitic history chiefly; but hemiplegia occurring in youngish people, apoplexy, and loss of intelligence, would be suspicious. As for prognosis, he has known cases to recover; but the prognosis is bad, as sudden death may occur at any time, or life may be prolonged. If deep coma occur, the result is inevitably fatal. In the way of treatment, he recommends the administration of mercury by inunction till salivation is effected, low diet, a sort of 'hunger-cure'; if iodide of potassium be used, it must be in doses from 30 to 150 grains in a day. If there be symptoms of anæmia of the brain, the patient must be kept in the horizontal position, and wine and digitalis should be administered.

PROFESSOR SCARENZIO has been appointed to teach operative surgery in the University of Pavia, in the room of the late Professor Porta.

DR. CONCATO, Professor of Clinical Medicine in the University of Bologna, has been, at his own request, transferred to the same chair at Padua; and is succeeded at Bologna by Dr. A. Murri.

TWO CLINICAL LECTURES ON THE CAUSES, THE PREVENTION, AND THE CURE OF LACERATION OF THE PERINÆUM. BY WILLIAM GOODELL, M.D., CLINICAL PROFESSOR OF DISEASES OF WOMEN AND CHILDREN IN THE UNIVERSITY OF PENNSYLVANIA, ETC.*

LECTURE I.

Gentlemen,—I bespeak your earnest attention this morning, because I hope to teach you how to avoid one of the worst of the non-fatal lesions which can befall a woman in child-birth, and to show you a simple operation by which you can assuredly cure her.

Next to subinvolution of the womb, the laceration of the perinæum is, perhaps, the most common lesion of labour; especially so among the poor, who are attended by midwives, by medical students, or by recent graduates. From an examination of the inmates of an institution to which I am attached, I find that in this class of society complete laceration of the perinæum takes place more often than once in a hundred labours, while, of course, the proportion of bad rents not involving the sphincter ani is much larger than this. So common, indeed, is this lesion that, judging from the past experience of our clinic, I shall this winter have occasion several times to perform before you the operation for the restoration of the perinæum. As an earnest of this, I now bring before you a woman who, in her first and only labour, met with the great mishap of having her perinæum badly torn. Instead of a close and symmetrical contact of the labia majora, look at this irregular and gaping opening, extending from the clitoris to the lower verge of the anus. The perinæum has disappeared; the upper segment of the anal ring is torn through; the rent extends up the rectum for at least an inch, and one great cloaca takes the place of the vulval and anal openings. For six years she has suffered from symptoms growing more and more distressing, until at last they have driven her to us for relief.

What the nature of these symptoms is you will best understand by consulting this diagram, which is reduced from Savage's excellent plate. From it you see that the floor of the female pelvis is made up of a mass of muscles so interlaced that hardly one of them has a special property which is not in a measure shared by the others. Upon removing the skin and superficial fascia, we come, midway between the lower vulval commissure and the anus, to a highly elastic and dense white tendinous structure, called the perineal body. It seems to be made up by the fusion of several muscles which meet there. Thus, the external sphincter ani, which starts from the coccyx, surrounds the anus, and is inserted in the perineal body. So, on each side, does the transversus perinæi. On the other hand, each sphincter vaginae, called also bulbo-cavernosus or compressor bulbi, arises below in the perineal body and sphincter ani, passes up around the vulval opening like a fleshy ring, and converges to meet its fellow over the dorsum of the clitoris. The property of this muscle is to pull down the rigid clitoris into contact with the male organ, to squeeze out the contents of the vulvo-vaginal glands, and to compress the dorsal vein, and also the bulbs of the vagina, so as to obstruct mechanically the current of blood and produce a turgescence of all these erectile organs. The levator ani is the next important and powerful

* From the *Philadelphia Medical Times*, November 1875.

muscle of this group. It arises from the ramus of the pubes and the spine of the ischium, and is inserted into the coccyx and the sides of the vagina and of the rectum. By these attachments, and by interlacements with the corresponding muscle on the opposite side, it and its fellow constitute the true constrictor of the vagina.

Now, without further comment, a mere glance shows that the loss of every fibre at the point of fusion of these muscles entails a corresponding loss of power in the floor of the pelvis, and a consequent impairment of support to the reproductive organs. The sustaining power of the vaginal column depends upon the integrity of its perineal abutment. It is the tonicity of the vaginal walls and the pelvic attachments of the uterus that mainly keep the nicely poised womb in place. These, in a case of torn perinæum, may not at once yield; but they will sooner or later; for air gains access to the womb, irritating and congesting it to such a degree that it will ultimately flex or prolapse from an acquired hypertrophy. The air thus sucked up into the vagina is very liable to escape audibly, constituting that very mortifying disorder which our Teutonic brethren call 'garrulity of the vagina.' The anterior wall of the vagina, being now unsupported, will descend, dragging with it the bladder. The greater the rent, the greater will be the dislocation of the pelvic organs, and the greater the evils entailed. Again, rents of this kind are attended with more or less impairment of the sexual functions. Thus, from the injury sustained by the perineal body, the vulva becomes enlarged, the vagina relaxed, the bulbs of the vagina but slightly compressed, and the sexual act blunted on the part of the male, and imperfectly responded to by the female. Partly from this lack of reciprocity, and partly from the necessarily shortened vagina, which rejects the semen as soon as ejaculated, the woman, like the patient before us, often remains barren. But should the rent traverse the whole perinæum, and divide the anal sphincter, or extend through the recto-vaginal septum, then, in addition to the above train of evils, there will be an involuntary escape of flatus, and an incontinence of the fæces when at all liquid. The woman's clothing is soiled without warning, her person becomes repulsive to her husband, and her company undesired by her friends. Seclusion and mental anguish undermine her constitution. Few calamities can be more grievous than this one. To keep her bowels costive, this woman takes a daily dose of opium. A young married lady, whose perinæum I restored not very long ago, got into the same habit. But, however bound her bowels were, she would soil her linen whenever it thundered or she otherwise became nervous. Every two or three weeks she was obliged to take an aperient, and would then have to spend many hours on the commode—seventeen hours on one occasion—after taking a dose of castor-oil. In order to spare herself the mortification of breaking wind before others, this lady shunned the society of her friends, and secluded herself in her bedroom. She did not even join the family at their meals, she never went out until after dusk, and never dared to ride in a street-car. Altogether, she was in a sorry plight. Since, therefore, the urgency of the symptoms, and since, also, as you will shortly learn, the chances of a successful operation depend upon the condition of the sphincter ani, laceration of the perinæum may, for all practical purposes, be divided into those which involve the sphincter and those which do not.

The causes of these lacerations may be summed up as follows: 1st, Rigidity, dryness, and congestion of the soft parts, as in first labours; 2nd, Absolute or relative disproportion between the size of the head or of the shoulders, and that of the vulva; this also includes the presence of one forearm, or both, along with the shoulders; 3rd, Every cause, whether moral, anatomical, or physiological, that precipitates the passage of the head through the soft parts—as, for instance, violent straining efforts through great nervous excitement, a small head, a straight sacrum, or an overdose of ergot; 4th, Faulty mechanism of labour, such as incomplete flexion or extension of the head; or an occiput rotating posteriorly; 5th, Keeping the limbs straight and in close contact at the moment of the birth of the head; 6th, Causes dependent on the physician, such as the use of the forceps, a faulty method of supporting the perinæum, or meddlesome midwifery.

For cases of rigidity, or of disproportion, or of an undersized vulval opening, anæsthetics will be found of great service. They will also restore moisture to a dry and congested perinæum, and curb uncontrollable expulsive pains.

Many lacerations are, in my opinion, owing to the common mistake of making so long continued and so firm a pressure on the perinæum with the hand as to make it hot, dry, and unyielding, and also to prevent it from undergoing an equable dilatation. The portion thus compressed cannot take its share of the general tension, and the strain is thrown on the fourchette. Further, the pressure of the hand, by obstructing the free circulation of blood, impairs the vitality of the perinæum. Bruised, congested, and benumbed, it is no longer a living tissue, capable of responding intelligently, so to speak, to the requirements of the occasion—when to repel, when to solicit the advance of the head; and this nice point nature can very generally determine far better than the physician. Again, the word 'support,' as applied to the perinæum, is a misnomer. No 'support,' in the ordinary acceptation of the word, is afforded to the perinæum by direct pressure. If such a method ever accomplish any good, it is by retarding the advance of the head; in other words, by supporting the head through the interposed perinæum, and not by supporting the perinæum itself. Why not then support the head by pressure directly applied to it, instead of through a medium which requires perfect freedom from all restraint in order to undergo the requisite and inevitable amount of dilatation? Finally, a majority of the advocates of 'support' contend that it is most needed at the very moment of expulsion. But the woman, in the agony of the final throes, is very likely to jerk herself away from the hand of the accoucheur. Of course, then, the perinæum, being abruptly released from the counter-pressure, is more liable to yield to a strain suddenly sustained for which its fibres are unprepared. Obstetric teachers recognise this danger, and in vivid language caution the student against it.

Although I believe that in the vast majority of labours the perinæum does best when let alone, yet cases do undoubtedly arise which demand intelligent assistance; nor can the line of demarcation be always drawn between natural and morbid conditions. Apart from a direct and retarding pressure upon the presenting part itself, the only manual aid that I permit myself occasionally to give is as

follows. Insert one or two fingers of the right hand into the rectum, and hook up and pull forward the sphincter ani towards the pubes. The thumb of the same hand is meantime to be placed upon the foetal head, scrupulously avoiding all contact with the perinæum. For this method I claim the following advantages. (a) By pulling up the sphincter ani towards the pubes not only is nature imitated, which always dilates the anal orifice, but the perinæum is brought forward without direct pressure, and its dilatation is diffused over its whole surface, causing a corresponding relaxation of the strain on the posterior commissure in the line of its raphé. In addition, its muscular fibres are crowded up to, and consequently strengthen, the line of greatest tension; just as a prudent general hurries up reinforcements to the point of attack. (b) The same force which dilates the sphincter ani compels the occiput to hug the pubes and favours extension, especially if the fingers in the rectum are hooked over the prominences of the foetal face or over the chin. (c) This aid is not liable to sudden interruption from the movements of the woman. (d) The thumb of the same hand, together, if needful, with the fingers of the free hand, can by direct pressure upon the presenting part restrain its too rapid advance, without exciting that reflex uterine action which is frequently evoked by the irritation of contact with the perinæum. (e) The circulation of blood remains free; the nerves are not benumbed by a double pressure, viz., by that of the hand and that of the presenting part; and the perinæum, therefore, continues in its natural condition, that of a living, elastic, and sentient tissue.

Misdirected traction on the after-coming head, viz., too much in a downward direction as the head is about to emerge, causes the chin to hook over the perinæum, and is in a primipara very commonly followed by a bad rent. The lesson, therefore, taught is, at the close of a breech-labour needing help, to turn the woman on her back, to separate the knees, and to carry the child's body well up between them. But in the majority of cases of laceration in which the sphincters ani are involved, you will, I am sorry to say, find, as in our patient, that the labour has been an instrumental one. Yet there are cases in which the very use of the forceps protects the perinæum. Thus, for instance, whenever the pubic arch is too narrow, the sacrum is too straight, or the head, in an occipito-anterior position, is over-flexed, and the vertex bears on the perineal centre and threatens to perforate it; whenever, in an occipito-posterior position, the head is too little flexed, the forceps is urgently needed. Why, then, is a forceps delivery so often the cause of injury to the perinæum?

To this question there are many answers. In the first place, through a false delicacy, many physicians deliver the child under the sheet; they work in the dark, and cannot see what they are about. In difficult forceps-cases, the physician, worn out by direct traction, is very likely to brace his foot, or even both feet, on the edge of the bed. The traction thus exerted is uncontrollable; and when the head passes the narrow brim, which it does usually with a jerk, its momentum cannot be checked before it has torn its way through the perinæum. Again, in cases requiring apparently but little traction, the use of the forceps will often occasion a slight tear in the vagina, which the passage of the shoulders prolongs through the perinæum. Delivery by the

forceps, even in skilful hands, will often produce laceration; for the head is liable to be brought down too quickly upon the unprepared soft parts; and it becomes a very nice point, indeed, to determine the exact moment when the head may be delivered with impunity. The cautious physician is liable to be caught, as it were, 'on the centre.' He sees or feels the perinæum stretched out to a perilous thinness, and the fourchette almost cracking under the strain. In doubt whether the moment has come to raise the forceps-handles and turn out the head, or to depress them and thus restrain its advance, he wavers, and in a twinkling the fibres part. On the other hand, the impatient physician is tempted to turn out the head before the parts are sufficiently dilated. Finally, what is not unfrequent, at the last moment the physician's courage fails him, and he lowers the forceps-handles just as the head is about to emerge—a course equally fatal to the integrity of the perinæum. From too hurried a delivery, or from faulty traction, I have seen so many bad rents attending the use of this instrument, even in practised hands, that I cannot withhold the opinion that, in the majority of cases, nature can accomplish the final delivery of the head through the soft parts much better than the physician. My advice to you, therefore, is that, other things being equal, as soon as the perinæum is well dilated you should remove the forceps, unless the blades are so firmly imbedded in the child's tissues that their withdrawal requires a force which might hasten the delivery of the head. This practice, if not so brilliant, you will, in the long run, find the safer.

Through sentiments of delicacy many lacerations of the perinæum escape the notice of the physician. I have operated on several cases in which the woman has assured me that the discovery was not made until the bowels, after a purge, had proved uncontrollable. After the delivery of the placenta, you should, therefore, make it a rule to introduce the index-finger into the rectum and the thumb into the vagina. By this double touch you can estimate the thickness of the intervening flesh, and thus determine whether an extensive laceration has taken place. If a rent be discovered, decently inspect the parts. By daylight this examination can usually be made without the knowledge of the patient. When candle-light is needed, you may be compelled either to make some excuse or boldly to explain your object. Sometimes a formidable hæmorrhage takes place from the perineal wound, and yet you will not discover its source unless you have all your wits about you. You will naturally infer that it comes from the womb, and will, accordingly, mistreat it by resorting to the usual remedies for *post partum* hæmorrhage. Make it, therefore, an inflexible rule to stretch open the vulva and visually examine the perinæum, whenever blood seems to escape from a firmly contracted womb.

Although labour is the common, yet it is not the invariable cause of these lacerations. Several cases are on record which happened from the breaking of a cracked chamber-pot. Women have been gored by cattle in this portion of the body. In sliding down the sides of haystacks they have been impaled by the handle of a rake, of a hoe, or of some other implement. But whatever the cause, the treatment is of course the same.

Since so large a share of a woman's health and happiness depends upon the integrity of her peri-

næum, what should be your rule of action when she meets with this injury? Unless the rent is simply cutaneous, or very slight indeed, and not extending much beyond the fourchette, it should not be left to nature, for nature is here too capricious to be depended on. You must perform the primary, or immediate, operation—that is to say, you must at once sew up the wound. Now, although this advice is sharply criticised by some very good authorities, I offer it to you with the greatest confidence of its soundness. The fears of septicæmia entertained by some physicians are purely hypothetical; for, although the suture tracks form, in one sense, new foci of infection, yet they close up a raw surface whose area is vastly larger than theirs. Should hæmorrhage be present, the sutures will invariably check it. Clinical experience proves that a very large measure of success follows the immediate operation. Further, it is far more rational to take advantage of the necessary confinement in bed after delivery, and to close the wound at once, while its surface is raw and the maternal soft parts are comparatively numb and insensible, than to postpone the operation to a time when the woman shall be nursing, when the cicatrised flaps shall demand quite a formidable and tedious operation for their denudation, and when a special confinement in bed for two weeks or more will be needed. Had the immediate operation been performed on this woman, she would most likely have been spared six years of suffering, and the tedious secondary operation which she has made up her mind to undergo next week.

My own method is, immediately after the delivery of the placenta to pass deeply two, three, or more wire sutures, securing each one by merely twisting its ends together. Each suture is entered about an inch from the cutaneous margin of the wound, and is made to emerge on the mucous membrane of the vagina very near to the edge of the raw surface. In addition, the first stitch must always be entered a little *below* the lower angle or fork of the wound. From the flow of bloody lochia, and also from the deep congestion of the soft parts induced by labour, you will not always find it easy to distinguish the raw surface from the mucous membrane. A good light, will therefore be needed. It will also be well to stuff a sponge high up in the vagina, and temporarily cork up the lochia until the sutures are passed. This sponge you will of course remove before the sutures are twisted together. Some very extensive rents are merely skin-deep. I have seen one extend nearly half round the anus without involving the perineal body or a single fibre of the sphincter. Such a rent is merely cutaneous, and needs superficial sutures only. The *serres-fines* will here be found very useful. They must be placed about half an inch apart, and made to grasp to their fullest extent both edges of the wound. The first one should nip the skin just below the fork of the wound, and the upper one just above its upper ends. If the edges of the rent are ragged, they should be trimmed off with the scissors. The *serres-fines* need not be kept on longer than forty-eight hours, and superficial sutures not longer than four or five days. When the laceration is not great, no other treatment is necessary excepting that of keeping the bowels bound for a week. But when the rent extends to or through the sphincter ani, or several deep sutures have been introduced, then the same precautions must be taken—viz., those of drawing off the urine, of bind-

ing the knees together, and of keeping the bowels costive, etc.—as I shall enjoin upon you when describing the after-treatment of the secondary operation.

(To be continued.)

ON MORPHIOMANIA. BY DR. EDWARD LEVINSTEIN, PRINCIPAL MEDICAL OFFICER OF THE ASYLUM AT SCHOENEBERG, BERLIN.*

GENTLEMEN,—Allow to me to direct your attention to a disease for which I can find no more appropriate name than morphiomania (*Morphium-sucht*). It has not yet been admitted into text-books; and only a few observations of it are recorded in medical literature (see Fiedler and Hirschfeld, in Kunze's *Zeitschrift für Praktische Medicin*, 1874).

The history of the disease is brief: it dates from the time when the method of subcutaneous injection by Pravaz's method became popular; and, in spite of the shortness of the time, it has gained a wide and dangerous extension.

Morphiomania arises from the abuse of morphia-injection; and the results of this abuse are disturbances of the whole nervous system. The originators and spreaders of the malady are physicians, who, in cases of more or less painful and long-continued diseases have allowed their patients to inject morphia subcutaneously; and it has been further spread by the patients themselves, who have recognised only the comfort produced by the injection, and not its dangers.

The symptoms of morphiomania are nearly the same of those of dipsomania; the similarity of the two diseases extend even to the delirium. In delirium tremens from alcohol and in delirium tremens from morphia, horrors, trembling, and hallucinations are pathognomonic; in both diseases, inflammatory affections of the lungs, intestinal, etc., run an equally severe course. They differ essentially in these particulars; in morphiomania, mania does not occur as a psychical form of disease; and, contrary to what is observed in dipsomania, the victims are almost exclusively found in the higher and more cultivated classes of society.

To those who frequently use injections of morphia, it becomes indispensable, in order to ward off all psychical and somatic uneasiness; and thus they take to morphia as the tippler to his dram. They deaden their mental worry, their domestic troubles, their social unpleasantnesses; as the alcohol-drinker does with his morning dram, they steady their tottering limbs with morphia; and, when the morphia has been excreted from the body, and the feeling of depression and discomfort, like that of alcoholic seediness, bring before their view their miserable and comfortless position, and the mental and corporeal break-up of their lives, a renewed dose of the poison helps them out of their misery, which is only in part of spontaneous origin. But the intervals in which they can lead an endurable existence without morphia become constantly shorter and shorter; the craving for morphia constantly increases, the vicious circle constantly closes in around them, until they become incapable of resistance and totally broken down.

I will relate to you the histories of three cases, re-

* Read before the Berlin Medical Society. *Berliner Klinische Wochenschrift*, November 27, 1875.

markable both with regard to the large dose and to the long-continued use of morphia.

A married pair, committed to my care by Medical Councillor Dr. Günther of Dresden and Professor Westphal of Berlin, were admitted into the *Maison de Santé* at Schöneberg on July 19, 1875.

The man was aged thirty-eight; he had been an officer, and was of strong build. Ten years ago he had learned the use of morphia in rheumatic pains, and during the last five years had injected daily a gramme (fifteen grains) of acetate of morphia.

His wife suffered for a short time from gallstone colic, for which she used injections of morphia. The war of 1870-71 taught her another indication for its use. She took to morphia to interrupt her sorrow, to make her forget her trouble at the dangers to which the nearest members of her family were exposed. During the last five years she had injected daily eight *decigrammes* (twelve grains) of morphia.

As a result of the condition which had been induced, the male patient had loss of sleep, increased reflex excitability, exalted and perverted sensibility, neuralgia, twitchings of the muscles, and dryness of the tongue. There was no constipation; and the pupil, instead of being contracted, was dilated. His face had a remarkably deep red colour; he perspired on the slightest exertion, often even while at rest, to such an extent that he was obliged to change his linen several times daily. The patient, though intelligent and in many respects well-informed, had no inclination for any business; he was stupid and exhausted, and felt himself ill.

His wife, aged thirty-three, had a grey-lead colour of the face; her pupils were scarcely as large as pin's heads. Menstruation had ceased for four years. She had hyperæsthesia and neuralgia, as well as violent rigors of the tertian type. Her appetite was small; animal food was especially disgusting to her.

Memory and judgment were well preserved in both patients.

I at once entirely cut off the supply of morphia from the male patient. In the case of his wife, I diminished the quantity daily, so that the use of morphia was ceased from altogether from the fourteenth day.

On the first day after the withdrawal, the male patient showed a high degree of irritability, writhed all over if one only felt his pulse, and had rigors and painful attacks of cough. On the second day he was much depressed, and so weak that he had to be carried to the bath, and dressed and undressed. In the evening diarrhœa set in, and continued fourteen days. With the diarrhœa, during the first few days, there were symptoms of congestion in the head and occasional vomiting. The patient behaved like a person in desperation; he craved most urgently for morphia, beat at his window and doors, etc. Doses of three grammes of chloral produced no sleep during the first three nights.

During the next three days the sensibility was still more heightened, and hyperæsthesia of the scalp and giddiness were present. On the last of the days, however, the patient began to eat and to feel more easy.

Four days after the commencement of the treatment, the patient slept without chloral, but with interruptions; during the sleepless hours of night he was excited, and was depressed during the day. At the end of the second week there was a cessation of the psychical and somatic effect of the withdrawal

of the morphia, with the exception of increased sensibility.

The temperature did not undergo any abnormal variations during the treatment. The patient gained about 2250 grammes (nearly 5 lbs.) of weight during the four weeks.

In the female patient the successive reduction of the morphia injected was attended with increase of reflex irritability and a feeling of extreme discomfort and loss of power. She was sleepless, and, when in bed, had a constant sensation of falling out. There were convulsive movements of the limbs, and neuralgia of the genital organs and bladder. She avoided her bed, as, if she lay in it, painful contractions of the arms set in. After the daily dose of morphia had been reduced to 5 centigrammes, moderate diarrhœa appeared and continued eight days; this was accompanied by anxiety, giddiness, palpitation of the heart, and redness of the face.

The patient, an intelligent and well-informed woman, lamented and wept like a child, was excited to a high degree, and incessantly cried for morphia. After three days, the redness of the face disappeared; the patient was very weak on her feet, and complained of pain in the region of the stomach and liver. Ten days after the total withdrawal of the morphia, the catamenia appeared and ran a normal course. After having been under treatment for four weeks, the patient left the institution, happy and cheerful, having gained 2,000 grammes (nearly 4½ lbs.) in weight.

The third patient was a man aged thirty-two, strongly built, of pale yellow complexion, hollow-eyed. The pupils were dilated; there was no constipation; virile power had been lost for half a year. For three years he had injected more than a gramme of morphia daily. On October 9, he entered the *Maison de Santé* in order to be cured of his habit of using morphia, as he had lost sleep and appetite, and was troubled with violent vomiting every morning.

The supply of morphia was at once entirely stopped. Twelve hours afterwards there were depression, weakness, melancholy, and clonic convulsions. The next day he had diarrhœa, which lasted nine days, and severe vomiting, which continued eight days. During the first five days he was quite sleepless, and had illusions and hallucinations of vision.

On the fourth day he had tremblings of the muscles of the face, tongue, and limbs; speech was difficult, and there were convulsive twitchings of the limbs.

On the fifth day, speech became still more difficult; the uneasiness and hallucinations of sight increased during the night and exhausted the patient. His voice was hoarse, tuneless, and hesitating; his aspect was one of depression.

During the fifth night, the patient, while sitting upright in his bed, suddenly fell backward on the pillow; his breathing stopped, and then became difficult and panting. He had the *facies Hippocratica*. After half an hour the pulse and respiration rose; but a high degree of collapse remained. On the sixth day the patient slept half an hour; and on the seventh day, after a bath with affusion, an hour and a half. Up to the eighth day the patient vomited all his food; his appetite then returned and the vomiting ceased. On the ninth day the patient felt somewhat more at ease; he said that he no longer had any desire for morphia, and was only troubled about his sleeplessness.

There was a rise of temperature to 38.5° Cent. (101.3° Fahr.) on the fourth night.

An almost daily examination of the urine in the married pair whose cases are first recorded showed on the first two days after the withdrawal of morphia a turning of the plane of polarisation to the left; on the other hand, Trommer's test, applied during the four weeks of observation, showed in both reduction of the hydrated oxide of copper. In the third case, there was no change in the plane of polarisation; but Trommer's test gave the same result as in the other cases. This reduction could not be due to chloral, as the female patient took it only a few times, and the last patient had none.

The symptoms of morphiomania are so distinctly defined in these cases, that it is not necessary to describe them more specially. It is worthy of notice, that the abuse of morphia produces almost the same pathological phenomena as those for which it is indicated as a remedy. Hyperæsthesia, neuralgia, sleeplessness, anxiety, depression, and irritability, are both overcome and produced by morphia. Further, when morphia is suddenly or gradually withdrawn, there is during the first days a considerable aggravation of the disturbance, especially of the cerebro-spinal and vaso-motor nervous system (feebleness of gait, trembling, various degrees of rigors, deep redness of the face, perspiration of the whole body).

As regards the prognosis of morphiomania, I will show that in a large number of patients I have seen only 25 per cent. of cases of recovery; in most cases there was a relapse. In two cases I have seen the abuse of morphia followed by marasmus and death; two other patients committed suicide. Five were drinkers; among these was the wife of a colleague, who had read in a book on *materia medica*, that alcohol was an antidote to morphia; she used it as a remedy to cure herself of the habit of using morphia, and fell a victim.

The treatment of morphiomania consists principally in the withdrawal of the morphia; and sudden is preferable to gradual withdrawal. The organism bears rough and energetic interference better than that which acts slowly, as we see in surgical and obstetric operations, etc. The treatment of the patients requires personal devotion on the part of the medical man, and is difficult and thankless.

To wean inveterate morphia-cravers from morphia is impossible, unless they be treated as prisoners. While the morphia is withdrawn they must be isolated, and be constantly watched by educated persons inaccessible to all attempts at corruption. Such persons are found with difficulty; for some secretly bring morphia to the patients for the sake of reward, and others cannot resist the pathetic entreaties and severe sufferings of the patients. Windows and doors must be closed against all communication with the outer world. The patient's clothes, the sofas, the cupboards in his room must be repeatedly examined; for it is characteristic of every morphia-craver who comes voluntarily or involuntarily into an institution to be cured of morphiomania, that he brings with him a large dose of morphia, and one or more injection-syringes. The physician must not rely on the promises or the most solemn assurances, or on the word of honour, which the patients willingly give. Morphiomania, like every passion, sets aside the character of the individual; the most educated, the most judicious and intelligent, eschew no means, no trick, to deceive the physician, and to either secure the morphia which they have brought with them or to procure a new supply.

If the physician be energetic, observe his patients

constantly, and have control over the watchers, and if these be honest, the most difficult part of the treatment is overcome in eight days.

After the morphia has been withdrawn twelve hours, collapse usually sets in; the patient should therefore keep his bed, and, during the first eight days, not be deprived of the use of stimulant wines; it is even necessary for women to take large doses of alcoholic liquors at this time. As has been shown in the third case, the collapse may become so severe as to endanger life. The danger is overcome by the subcutaneous injection of liquor ammoniæ anisatus, followed soon by an injection of fifteen milligrammes of morphia.

If, during the first forty-eight hours after the withdrawal of the morphia, the patient do not groan and lament, if he be able to eat during the first days, and if his countenance be animated, he has, in spite of denial, secretly used morphia. The narrowness of the pupils, and the absence of diarrhœa, will soon confirm the impression.

The distress, restlessness, and despair which affect the patients during the first three days, are so severe, that the physician must be deeply penetrated by the task which he has imposed on himself to look calmly on this misery, and to have no ear and no heart for the despair, lamentation, and weeping.

Attempts at suicide on the part of the patients, which their unhappy frame of mind may lead them to make, must be watched against and prevented.

Prolonged baths should be given, both as a remedy for the neuralgia which appears during the time of abstinence, and to promote sleep at night; and, if there be not too great collapse, they should be combined with cold affusions.

Diarrhœa, which in the cases observed by me has almost always set in immediately after the withdrawal of the morphia, is an obstacle to treatment only when it becomes exhausting. The injection into the rectum two or three times a day of one to three litres of water at blood-heat aids in soon assuaging this symptom.

Vomiting, which in some cases appears during the first days of abstinence, and which yields to no remedies, as in general narcotics must be excluded from the treatment, demands that care be taken for the feeding of the patient by the rectum. Leube's nutritive enemata are very useful in these circumstances.

As morphiomania has an affinity with dipsomania, the use of wine and alcoholic liquors should not be prohibited altogether, but should be limited from the time when the patients begin to take regular nourishment. The further treatment must be regulated by the general condition of the patient. Fresh air, good nutritious food, and preparations of iron, will soon again raise the depressed powers.

Beyond all, however, it is necessary, even before the end of the third week of treatment, to provide bodily and especially mental occupation for the patients.

Experience teaches that the internal use or subcutaneous injection of morphia, so long as it is carried out by the physician himself, does not lead to morphiomania; and that this disease was first developed when physicians entrusted the administration to the nurses and attendants of the patient, and prescribed morphia injection. The reason which we often hear assigned for this, that the physician is hindered from making the injection personally, is not valid; he can then content himself with the internal administra-

tion of morphia, as, though the effect is a little slower if it be given *per anum* and on an empty stomach, it relieves pain and produces sleep just as much as when injected subcutaneously. The internal use of morphia is not attended with the very unnecessary feeling of comfort which makes morphia a source of pleasure to patients and stimulates them to its continued use.

I am aware of the great and almost insuperable difficulties which stand in the way of carrying out my requirements; but there is no other means of preventing the further spread of morphiomania.

The suggestions and objections made when I read a paper on the subject at the meeting of naturalists at Gratz, were chiefly the following. On the one hand, no reason was found for entrusting attendants on the sick with the injection of morphia. There may be exceptions: as a rule, one will become convinced of the disadvantages attending the practice. On the other hand, it was suggested that the legislature should be urged to enact a law forbidding apothecaries and druggists, under pain of severe punishment, to sell morphia to unauthorised persons. Such a law is already in existence; and yet a great number of apothecaries sell morphia to anyone who asks for it. Again, it is often impossible to make the apothecaries answerable, as they themselves are deceived by false prescriptions.

The last proposal, which was approved of, and which certainly can have no happy results, was, that in each case the physician should inform against the apothecary. But the function of an informer does not suit everyone's taste. With regard to the danger which threatens society through the spread of the malady, it was regarded as a duty of every physician to make subcutaneous injections of morphia personally. The much-occupied practitioner must limit himself to the internal use of morphia if he cannot carry out this requirement.

In the hands of the physician, the method of subcutaneous injection is a blessing to mankind; in the hands of the laity, it is a curse.

I conclude, gentlemen, with entreating you to direct your attention to this new form of disease. If you use your influence by word and writing, then, but only then, will its further development be arrested.

ON OBLITERATIVE ARTERITIS. BY DR. CARL FRIEDLÄNDER, PRIVATDOCENT AND ASSISTANT IN THE PATHOLOGICAL INSTITUTE AT STRASBURG.*

In the following lines I propose to direct attention to an extremely wide-spread affection of the arterial system, which hitherto has remained almost unknown.

1. I refer to the development of a connective tissue, very rich in cells within the inner coat of the middle and smaller arteries, which leads to a narrowing of the lumen, and at last to complete filling of the lumen with firm material, and obliteration.

2. The affection begins in the acute stage with a proliferation of small thickly crowded round cells, between the inner elastic lamella and the epithelioid lining. The cells afterwards increase in size, a larger or smaller quantity of intercellular substance

appears, the tissue acquires the character of granulation-tissue, or even of mucous tissue (there being, however, no mucin reaction); new vessels are also observed, often even small arteries, proved beyond doubt to be such by the presence of circular muscular fibres.

3. The proliferation either takes place at all points of the periphery simultaneously, so that a gradual concentric constriction of the lumen is produced, or with greater intensity on one side than on another. In the latter case, a transverse section has the form of a meniscus. The lumen is then narrowed on one side, and has an excentric, often quite peripheral, position.

4. The character of granulation-tissue is either retained by the proliferated layer for a long time, or it passes into a firm and, in some circumstances, perfectly sclerotic connective tissue, such as is found in firm fibromata. And this takes place everywhere when processes of sclerosis and induration go on around the artery; thus it especially occurs in callosities and warts, in the indurated edges of ulcers, in chronic metritis, etc. As the contraction advances, the wall of the vessel is thrown into folds. The muscular structure of the wall of the vessel is in the latter cases often entirely replaced by connective tissue, so that the limits of the artery are only distinctly indicated by the elastic layers, especially that of the inner coat. In other cases, the whole of the arterial coats become converted into a peculiar homogeneous slightly glistening substance, in which even the elastic layers disappear. The homogeneous substance contains only few or no cell-elements, and resists the action of acids, etc. I have also observed moderate caseation of the arteritic proliferation in arteries, the walls of which contained cheesy abscesses. On the other hand, fatty or cutaneous degeneration of the elements occurs quite exceptionally, if at all.

5. It may be laid down as a general law, that the wandering elements of the arteries also, on their part, take a considerable part in the great group of interstitial processes. According as acute inflammation (collective of small round cells), or formation of granulation tissue (in chronic inflammation), or induration, or caseation, takes place in the interstitial tissue supporting the vessels, the corresponding processes take place in the arterial wall itself, especially in the inner coat.

6. On the other hand, obliterative arteritis only rarely occurs as a primary affection. The 'syphilitic disease of the cerebral arteries,' expressly described by Heubner in his well-known monograph (which is a typical obliterative arteritis, presenting throughout no anatomical characters specifically indicative of syphilis, and being etiologically also in no wise limited to syphilis), occurs, indeed, in some cases apparently as a primary disease; while in other cases, in fact the majority, it occurs altogether as a result of meningitis or new growths. The consequences of this affection have been so carefully and completely studied by Heubner, that I have nothing to add to his description. [See page 50.]

7. As primary arterial processes we have to consider those which are observed in the normal closure of arteries; e.g., in the closure of the ductus Botalli and of the umbilical arteries. This obliteration does not at all take place through thrombosis, as is often incorrectly taught, but essentially through proliferation of the arterial walls, as has already been determined by previous researches, and espe-

* *Centralblatt für die medicinischen Wissenschaften*. January 22.

cially by the proliferation of the inner coat. We thus have a well marked 'physiological type' for the affection under consideration.

8. While obliterative endarteritis plays a more or less prominent part in the interstitial inflammatory processes of most other organs, its occurrence in the conditions affecting the lungs is of quite exceptional importance. Not only does it occur regularly, and in a very high degree, in the so-called indurative processes, in cicatricial bronchiectasis, etc., but it is a very important link in the chain of previous changes which lie at the foundation of pulmonary phthisis. It is almost impossible to closely examine a case of pulmonary phthisis without being struck with the large number of vessels that are in this way nearly or quite shut off from the circulation. And this remark refers not only to parts lying near ulcerated surfaces and centres, in which arteries changed into solid cords have long been observed (those not being, as is usually supposed, the consequence of thrombosis, but only a result of obliterative arteritis without any preceding thrombosis); but the endarteritic proliferation is very frequently, almost constantly, found in recent lobar and lobular inflammations, which, at a later period, lead to phthisical conditions. In these inflammations, as Buhl has shown, there is always found at a very early stage proliferation of the interstitial tissue of the lungs.

9. In the diseases analogous to phthisis, artificially produced in animals (such as pulmonary affection in rabbits after section of the inferior laryngeal nerves), the diseases of the arteries appears within the first few days (it may be at the end of forty hours); and the process may here be very well followed from its first beginning.

10. In these conditions, the idea impresses itself on the mind that the arterial proliferation must, through the ischaemia produced by it in the affected parts, have an essential share in the malignant course of the processes referred to. That this proliferation must stand in the most direct relation to the increase of pressure in the pulmonary arterial system, and to the dilatation and hypertrophy of the right heart frequently occurring in phthisis, and their results, is self-evident.

11. It further deserves to be pointed out that, both in the interior of tumours of various kinds and in the parts around them, obliterative arteritis is very regularly found. It occurs in simple granulation growths, in gummatous tumours, very frequently in tuberculosis with commencing chronic inflammatory or ulcerative processes, and more rarely in sarcomata. On the other hand, it is regularly to be observed in fibromata, and in the highest degree in elephantiasis, in which it often presents very distinct naked-eye evidence. In cancers also it occurs to a great extent where the elements of connective tissue are strongly developed; thus it is especially found in scirrhus.

12. As regards the origin of the cells, of which the proliferation in the inner coat consists in the first stages, it is clear that they have a triple source. *a.* From the epithelioid lining (for in the smaller arteries at least there are no other cell-elements in the inner coat); it must be assumed that the epithelioid cells have produced a new brood, while they themselves have remained in complete integrity as a continuous layer. (I have many times observed division of nuclei in the epithelioid cells, that is, multinucleated forms, even giant-cells themselves.)

b. Elements from the arterial blood may become insinuated between the epithelioid cells. *c.* Migratory cells may be furnished from the vasa vasorum in the membrana adventitia. Probably all these three modes come into action; from analogy, the third-named must in any case play an essential part. This is supported by direct observation, which I will not here describe more particularly. I will only remark that in all cases where proliferation is found in the inner coat, accumulation of cells is present in the adventitia.

13. Obliterative endarteritis shows in its whole course the most complete agreement with the processes which take place in the organisation of thrombi. An organised thrombus, or, to speak more correctly, the tissue which is found after some weeks in the place where a thrombus has been, may have the closest resemblance to a vessel closed by obliterative endarteritis or endophlebitis. The earlier thrombus is generally recognised by the remains of pigment; but if we put aside this unessential circumstance, or look at cases in which the pigment is absent from the first, as in white thrombi (Zahn) it is only in respect to the very first commencement that an essential difference between the two processes can be proved. The hypothesis may then be advanced, that the organisation of thrombi takes place by a process analogous to obliterative arteritis or phlebitis. Very instructive in this respect are the conditions of the arteries and veins in the placental portion of the uterus after labour. Immediately after birth, one part is found almost empty and collapsed; another part is filled with fluid blood; and a third with coagulated blood and thrombotic material. In all these three cases the process of obliteration or organisation, so far as can be seen, takes place in all essential points in a perfectly identical manner.

14. Finally, I have to remark, that in veins also, in interstitial inflammations, nearly similar obliterative processes are often enough to be observed, though not with the same regularity as in arteries. The determination of the condition is often more difficult in veins than in arteries, since the inner coat of veins, in consequence of the less development of its elastic elements, appears much less distinctly defined than that of arteries. Moreover, thrombosis occurs as a complication much more frequently in veins.

15. On the other hand, it is interesting to observe that a similar obliterative process, by means of new formation of connective tissue, occurs also in the interior of membranes bearing epithelium, and is generally preceded by destruction of the epithelial cells. The conditions are apparently interstitial proliferation processes in the neighbouring parts. This is not unfrequently observed in the smaller bronchial tubes in cases of chronic indurative pneumonia; also in the secretory ducts of glands, as in the lactiferous tubes in cases of scirrhus of the breast, and also in simple fibromatous and chronic inflammatory conditions of the mamma.

I hope to make a further communication on this subject in the course of next month.

ANATOMY AND PHYSIOLOGY.

BROWN-SÉQUARD ON CAUTERISATION OF THE CEREBRAL LOBES IN THE GUINEA-PIG.—Brown-Séquard (*Progrès Médical*, 1875, no. 16) observed

after deep cauterisation of one side of the brain a peculiar spread out position of the tips of the toes, but no paralysis of the limbs of the corresponding side. He refers this to a disturbance of the 'muscular sense' of the corresponding side. The injury to the brain, which produced paralytic phenomena of the corresponding (not of the opposite) half of the body, influences, according to the author, remote parts of the brain, upon which the normal functions of the affected extremity depend. The establishment of this hypothesis is wanting.

NESTEROFFSKY ON THE NERVES OF THE LIVER. M. Nesteroffsky (*Virchow's Archiv*, Band lxiii. p. 412) by the gold method and the subsequent addition of ammonium sulphide, succeeded in demonstrating the nerves in fresh sections of frozen injected liver. The nerves of the liver end in the form of networks, which surround the blood-capillaries; and the terminations of the nerves have no connection with the liver-cells.

ARNOLD ON THE CONDITION OF THE WALLS OF THE BLOOD-VESSELS DURING EMIGRATION OF THE COLOURLESS BLOOD-CORPUSCLES.—J. Arnold (*Virchow's Archiv*, Band lxii. p. 487, and *Centralblatt für die Medicin. Wissenschaften*, no. 49), injected a weak solution of silver into the blood-vessels of frogs, in which single parts of the body had been inflamed twenty-four hours previously. The appearances of the so-called endothelial figures varied considerably from the normal. The 'cement-lines' appeared as broad, strong, zig-zag lines, or were only indicated by rows of granules.

There are large dark points in them, the stigmata; and in the cement-substance as well as in the stigmata are to be found white corpuscles in the act of passing out of the vessels, and this in various stages of their passage. Not unfrequently several colourless corpuscles are to be seen attached to one part of the cement substance, or to one of the stigmata; thus, two corpuscles may be lying within the vessel, and fixed by short processes in a stigma, whilst a third one for the most part has penetrated and only remains in connection with the vessel by means of a short process. Sometimes the accumulation of the white corpuscles on the outer side of the vessel, in the neighbourhood of the stigmata, is so considerable, that the sheath of the vessel, at the corresponding spot, stands out like a little hump from the epithelial layer. From this the author concludes, that the white blood-corpuscles in inflammation pass through the wall at the cement-substance, *i.e.* the stigmata; whilst, on the contrary, he never saw that other parts of the wall of the vessel, *e.g.* the epithelium, was permeable to the white blood-corpuscles. (See L. Purves, whose experiments were made in Donders's Laboratory in Utrecht in 1873, *LONDON MEDICAL RECORD*, vol. iii. p. 37.)

From experiments made with gelatine and fine vermilion injections, it seems that, in addition to the pronounced wandering out of colourless blood-corpuscles connected with disturbances in the circulation, other corpuscles also pass through the wall of the vessel; and apparently this also happens at the portion of the stigmata and cement-substance. When blue-coloured gelatine instead of the vermilion was employed, the inflamed vessels at numerous spots here seemed to be covered with small roundish blue protuberances, or with more elongated blue pro-

cesses. From this it results, that the wall of the vessel permits not only substances in solution to pass through it at the position of the stigmata and cement substance, but also a colloid body (gelatine), and other elements (vermilion.) The masses which have passed through the vascular walls, penetrate in the direction of the 'juice-canals' ('*Saftcanalsystem*') in the tissue, and under certain circumstances these can be completely filled laterally with the injection mass. Still the configuration of this system of spaces when injected is variable, according to the disturbances of the circulation which have occurred in the tissues. Whilst the juice-canals during venous stasis possess a broad and ampullated form, they appear smaller and more zig-zag in those disturbances of the circulation which are specially characterised by the exit of white blood-corpuscles.

BERT ON THE QUANTITY OF OXYGEN ABSORBED BY THE BLOOD AT DIFFERENT BAROMETRIC PRESSURES.—According to P. Bert (*Comptes Rendus*, tome lxxx. 733, *Centralblatt für die Medicinischen Wissenschaften*, no. 55, 1875), hæmoglobin forms with oxygen a chemical compound, which can be obtained by shaking blood with atmospheric air. Increase of pressure is without influence on this combination. More oxygen is taken up, but only corresponding to the absorption of this gas by the fluid, following Dalton's law. A diminution of the pressure to one-eighth of an atmosphere, at a temperature of 60° Fahr. has very little influence on the oxyhæmoglobin; from this limit onwards, however, it rapidly decomposes. The decomposition occurs earlier at a temperature of 104° Fahr. This is a cause of the poverty of oxygen in the blood of animals, which are subjected to an increasing diminution of pressure; a second cause is, that the contact of the blood with the air in the lungs is not sufficiently intimate to influence the degree of saturation with oxygen corresponding to the pressure and temperature. For this reason, the quantity of oxygen in the blood in experiments on animals is always smaller than in experiments outside the body.

PLÓSZ AND GYÖRGYAI ON PEPTONES AND FEEDING WITH THE SAME.—P. Plósz and A. Györgyai (*Pflüger's Archiv*, Band x. p. 536; *Centralblatt für die Medicinischen Wissenschaften*, no. 55, 1875) have performed a new experiment on the nutritive value of peptones, on an adult dog which had fasted for several days. They fed it with solution of peptones and the necessary nutriment free from nitrogen, estimated the quantity of nitrogen in the total excreta of the animal, and compared it with the known quantity of nitrogen in the food. During the whole experiment there was, nitrogen taken in, 14,451 grammes; nitrogen excreted, 13,463 grammes; 0,988 grammes were therefore retained in the body (under the assumption that the quantity of nitrogen can be accurately measured under these circumstances!). The body-weight rose from 2,531 grammes to 2,790, *i.e.* 259 grammes. Corresponding to the nitrogen deficit in the excreta, one can assume that during the feeding with peptones an addition of albumen had taken place, that the peptones can certainly be changed into albumen and employed for the building up of cells.

Another question of course arises, How far can peptones introduced into the body be followed as such? For the solution of this question, the authors injected 20 to 30 grammes of a watery solution

of peptones into the stomach of dogs which had fasted for forty-eight hours, and then killed them after two or four hours. As a test for peptones they employed the reaction of caustic potash and sulphate of copper (purple-violet solution) or boiling with Millon's reagent and nitric acid (yellow colouration). The greatest quantity of peptone by this process was found in the blood of the mesenteric veins and in the extract of the mesentery. The liver contained much less; indistinct traces were found in the blood of the hepatic vein and blood of the carotid artery. On injecting peptones into the veins, a part appeared unchanged in the urine, the larger part remaining in the body, and undergoing further changes. In the blood of the carotid, after three hours, a small quantity of peptone was still traceable. Lastly, the authors conducted blood, to which peptones had been added, in an artificial circulation through the amputated hind quarters and extremities of a large dog just killed (excluding the glands). The circulation lasted four or five hours. Here also the blood lost part of its peptones; in one case twenty grammes of peptones disappeared from the blood. After finishing, the blood was washed out of the vessels with a solution of common salt, and a watery extract of this as well as of the tissue was then made. Neither peptone, nor any other nitrogenous body which one might expect as a derivative of the albumen, was present.

W. STIRLING, D.Sc., M.D.

LÉPINE ON THE MOTOR CENTRES OF THE ENCEPHALON.—Lépine (*Gazette Médicale de Paris*, no. 25, 1875) with Rochefontaine and Tridon, has made experiments upon the influence of stimulation of distinct parts of the brain on the blood-pressure, heart, and secretion. Stimulation of the post-frontal convolution of a curarised dog with very weak induction shocks, produced a pronounced increase of the blood-pressure in the crural artery (seven centimètres of mercury). A certain time elapses before the increase of pressure occurs. The same result can be produced by stimulation of the prefrontal convolution and the corresponding part of the sulcus. If the point of the surface of the brain, which in a non-curarised animal discharges movements of the opposite feet, be stimulated with very weak currents, the temperature of this foot rises several tenths of a degree. The temperature of the foot of the opposite side rises, but not so high, whilst that of the rectum remains unchanged. The vessels of the brain and pia mater dilate and bleed more, but whether in consequence of the vaso-dilator influence of the stimulation on the cerebral vessels, or in consequence of the increased blood-pressure, is uncertain. No such result is observed after stimulation of the surface of the posterior lobes or of the dura mater. Stimulation of the spots which caused increase of the blood-pressure accelerated at the same time the heart-beats. With intact vagi and very strong current, there is a reduction of the number of heart-beats. Stimulation of points, whose locality is not defined, increases the secretion of saliva.

OTT ON THE ACTION OF LOBELINA.—In the *Philadelphia Medical Times* for December 11, 1875, Dr. Isaac Ott describes a series of experiments made by him with lobelina, and arrives at the following conclusions.

1. Lobelina, like nicotina and conia, paralyses the motor nerves.

2. Lobelina does not destroy the functions of the sensory nerves or the striated muscles.

3. Lobelina, nicotina, and conia depress the excitability of the spinal cord.

4. Lobelina destroys voluntary movement and co-ordinating power.

5. It temporarily decreases the pulse, followed by a subsequent increase, often beyond normal. Nicotina does the same. Lautenbach states that conia increase the heart-beat.

6. This action on the pulse is due to an action on the cardio-motor ganglia, provided that atropin paralyses the cardio-inhibitory ganglia.

7. Lobelina, nicotina, and conia temporarily decrease the pressure, followed by a rise much beyond normal.

8. This increase of pressure is due either to a peripheral vaso-motor action, or to an excitation of the spinal vaso-motor centres.

9. Lobelina, nicotina, and conia paralyse the pneumogastriacs.

10. In large doses it paralyses the vaso-motor centre, both to direct and indirect irritation.

11. Lobelina, nicotina, and conia accelerate the respiratory movements.

12. After section of the vagi, lobelina and conia cause no increase of respiratory movements.

13. Lobelina increases and then decreases the temperature; nicotina and conia decrease the temperature.

SCHMIDT ON THE INVESTIGATION OF BLOOD-SERUM, WHITE OF EGG, AND MILK BY DIALYSIS THROUGH GELATINISED PAPER.—Alex. Schmidt (*Pflüger's Arch.*, vol. xi., and *Centralblatt für die Medicinischen Wissenschaften*, no. 1, 1876) announces that the so-called English parchment-paper employed by him is not parchment-paper at all, but only a kind of ordinary writing-paper very carefully prepared with alum and gelatine. Of the paper 100 grammes yield to boiling water a mean value of 4.11 grammes of gelatine, 0.64 gramme of potash-alum, and 0.79 of other soluble salts. The quantities of gelatine and alum which at ordinary temperatures pass into the alkaline solution of albumen or into the diffusate are very small, so that this impurity need not be taken into consideration. The author prefers De la Rue's paper purified by extraction with dilute hydrochloric acid and water, and then covered with a thin coating of gelatine. Steeping for a short time in a one per cent. solution of gelatine is sufficient for this. The author then gives the method he employs for estimating the albumen in blood-serum, etc. The blood-serum is neutralised, coagulated with ten times its volume of alcohol, allowed to stand for twenty-four hours, then boiled, filtered, the coagulum washed with a mixture of ten parts of alcohol and one part of water, then with absolute alcohol, and lastly with ether. The soluble salts contained in the fluid remain in solution, the coagulated albumen only contains the insoluble earthy phosphates. On employing gelatinised paper, the quantity of albumen which passes through the paper is not inconsiderable; if the dialysis is continued for two or three days, and the water changed very often, then the greater part of the albumen passes through. The author considers 1, blood-serum and egg-albumen; 2, milk.

1. *Serum and Albumen*.—If diluted serum or solutions of egg-albumen be dialysed, there first occurs a stage at which the solution no longer coagulates on being boiled; it has an alkaline reaction, and still contains traces of salts. As the dialysis proceeds the reaction becomes neutral, the solution of

albumen is free from soluble salts, and, on burning, leaves only earthy phosphates. If an acidulated solution be subjected to dialysis, it still remains for a time capable of coagulating, even when all salts have been removed from it, and continues so until the last trace of acid has passed out. The quantity of earthy phosphates contained in the albumen continually diminishes with the duration of the dialysis, and not only absolutely, but also relatively to the quantity of albumen—to 0.194 per cent. of albumen. The soluble condition of the albumen therefore depends neither upon the quantity of alkali nor on that of the earthy phosphates. *Albumen is rather a substance soluble by itself in water.* The earthy phosphates pass into the diffusate in combination with a nitrogenous organic body, and remain in solution after the removal of the albumen which has passed into the diffusate.

2. *Milk.*—The former observations of the author upon this subject are here mentioned, that acidity of the milk diffusate also takes place even when paper free from alum is employed, so that it does not depend upon the presence of this substance, but is altogether absent in some cases. A certain part of the diffusate does not undergo the acid reaction; if, after the removal of all soluble salts and the milk sugar, the diffusate now resulting is separately collected, a fluid is obtained which, in addition to earthy phosphates, contains only certain organic substances, and shows no tendency to become acid. Like the albumen, a part of the casein also passes through the paper. Milk purified by dialysis conducts itself very peculiarly with regard to rennet. At first the capability of the milk for coagulating is increased by the rennet—i.e., the coagulation occurs at a lower temperature, and the cause of this phenomenon is the removal of the alkaline salts, which prevent the coagulation; on continuing the dialysis, however, the milk becomes quite incapable of being coagulated by rennet, therefore by the process of dialysis *some substance must have passed out*, which determined the *coagulation by rennet*. This property of being coagulated by rennet, can be again restored through the addition of the diffusate of milk, nevertheless only the diffusate obtained from milk which has become acid during the dialysis acts in this way, acidity of the diffusate arising spontaneously does not suffice.

In conclusion the author rejects the view of Heynsius, who ascribed the absence of coagulability in the solutions of albumen employed by Schmidt to the presence of alkalis (LONDON MEDICAL RECORD, October 15, 1875.) Schmidt asserts that Heynsius had no solutions quite free from salts, and that completely neutral solutions of albumen when quite free from salts do not coagulate either upon heating or on adding alcohol.

HEIDENHAIN ON THE PANCREAS.—R. Heidenhain (*Pflüger's Arch.*, vol. x., and *Centralblatt für die Medicinischen Wissenschaften*, no. 2, 1876) observed the following appearances were successively presented by the cells of the pancreas at the different stages of digestion.

1. During hunger the granular inner zone occupies the larger, the homogeneous outer zone the smaller part of the cells. 2. In the first period of digestion, during which a plentiful secretion occurs, there is diminution of the entire cells by using up of the granular inner zone, then addition of new materials to the outer zone, so that this becomes enlarged.

3. In the second period of digestion, during which the secretion diminishes and comes to a standstill, there is a new formation of the granular inner zone at the expense of the homogeneous outer zone, most pronounced diminution of the latter, increase of all the cells. 4. With long-continued hunger there are gradual increase of the latter to their original dimensions, and therewith slight diminution of the inner zone. During the state of physiological activity there is a continual change in the cells—metamorphosis internally, addition of matters externally. Internally there is conversion of the granules into secretory constituents, externally employment of the nutrient materials for the formation of the homogeneous substance, which again becomes converted into granular masses. The average appearance of the cells depends upon the relative rapidity with which this process occurs. In the first period of change there is a more rapid consumption internally and more rapid addition externally; in the second period, the most rapid changes occur at the limit between the outer and inner zones, in that the substance of the former becomes converted into that of the latter. During the condition of hunger the consumption is at a minimum, the addition takes place also slower, but it is still obvious in the apparent increase of the outer zone, which had almost disappeared. Corresponding to these histological changes, the chemical and experimental results of the author showed that pancreatin ready prepared (albumen-ferment of the pancreas), does not exist in the living gland-cells but only its peculiar mother-substance, and under certain circumstances pancreatin becomes free. This mother-substance, which Heidenhain calls 'zymogen,' is probably a compound of pancreatin with an albuminate. With plentiful secretion from the gland, the quantity of zymogen diminishes, to be again generated during rest of the organ. This process of regeneration does not occur sufficiently in a gland with permanent fistula, as soon as the secretion has become continuous.

Further, it is shown that the secretion of water by the gland can be influenced by the medulla oblongata; and, from the author's experiments, it is extremely probable that the excretion of the solid constituents of the gland-cells and that of water do not go hand in hand, but that each seems to be under the direct influence of the nervous system. The formation of pancreatin is connected with the complicated decompositions in the secreting cells, the development of a free acid playing a part in the process.

HERMANN AND STEEGER ON HÆMOGLOBIN.—L. Hermann and Th. Steeger (*Pflüger's Arch.*, vol. x.) contribute a paper on this subject. From the observations of Lothar Meyer, Pflüger, and Zuntz, we know that by adding an acid to blood only the smallest part of the oxygen of the hæmoglobin can be obtained by a vacuum. The cause of this phenomenon is to be sought for in the decomposition of the hæmoglobin, the oxygen being held fast by a decomposition product. For this purpose arterial blood was passed into a flask with warm water (176° to 194° F.) which was connected with the vacuum. About one-third of its oxygen was obtained by pumping. It was now necessary to see whether oxygen alone showed this property of combining with the decomposition products, or whether other gases, which also form compounds with hæmoglobin showed the same property. For deciding his ques-

tion blood saturated with carbonic oxide, and in another experiment with nitrous oxide, was conducted into the same flask. From the former only 1·7 to 1·8 vols. per cent. of carbonic oxide was obtained; from the latter, 4·9 vols. per cent. nitrous oxide and oxygen. These gases are also fixed by the decomposition products resulting from the rapid decomposition of hæmoglobin.

PATHOLOGY.

SCOTTINI ON BRACHIAL NEURALGIA PRODUCED BY A LATENT SARCOMA.—In the *Annali Universali di Medicina e Chirurgia* for July and August 1875, Dr. Scottini relates an interesting case which came under his notice in the hospital of Pavia.

A woman, aged forty-one, was admitted on February 7. Seven years previously she had pains in the pelvis and metrorrhagia, and the presence of a small uterine tumour was detected, which went on increasing in size. The reason of her entering the hospital on this occasion, however, was the existence of a constant painful feeling of weight in the left shoulder, passing down to the elbow and wrist. Nothing abnormal could be detected to account for the pain; her general condition was good. The disorder was considered to be rheumatic neuralgia, and was treated accordingly, with little or no relief; while the limb became gradually atrophied. It was then suspected that there was some grave alteration in the course of the brachial plexus or at its origin. On March 25 the patient began to have a sense of weight in the right upper and left lower limbs, and could not move them perfectly; then the right lower limb was attacked. On March 30 the feeling of weight, with formication, spread over the whole body; and on the 31st she died.

At the necropsy a small red tumour, as large as a hemp-seed, was found lying in a niche in the grey matter of the posterior part of the right cerebral hemisphere, at the level of the centrum ovale of Viussens. Under the microscope it was found to consist principally of giant-cells with abundant nuclei, along with large yellowish granular cells, and some relatively smaller cells with large nuclei, some round, some elongated; and there were also five nuclei, drops of fat, fibrils of connective tissue, and fusiform cells. In the posterior nucleus in the grey matter of the cervical portion of the spinal cord lay a tumour of the size of a filbert, nearly similar in structure to that already described. There was

adenoma of the thyroid body; and the lower lobe of the left lung contained some nodules consisting of numerous epithelial cells, large angular or elongated cells with large nuclei, spindle-cells, and many nuclei. At the apex of the chest on the left side was a tumour of the size of a small orange, whitish on the surface, and having red streaks of blood-vessels; it was formed of many round lobules, and was of fleshy consistence. It extended from the clavicle to the third rib, and pressed on the brachial plexus and the apex of the lung. It consisted of very large round cells, of giant-cells with abundant nuclei of various forms and sizes, of large and small free nuclei, and of some fatty granules. The uterine tumour was in one part partly softer than elsewhere; and the softened portion presented a structure similar to that of the thoracic tumour. The aorta and the iliac and femoral arteries contained coagula, in which were yellow spots consisting of giant-cells, very rich in small nuclei.

In commenting on this case, Dr. Scottini remarks that the uterine tumour was during the patient's life diagnosed as a fibroma, and that there was no sign of its having undergone malignant change. There was no indication during life of the small tumours in the brain and spinal cord. He believes that these were of recent growth; that the tumour in the chest was of much older origin; and that the changes which the uterine tumour had undergone did not commence until a still more advanced stage of the patient's illness.

MASCHKA ON A CASE OF APPARENT HYDROPHOBIA DEPENDENT ON CYSTICERCUS IN THE BRAIN.—In a paper quoted in the *Gazzetta delle Cliniche* for November 2, Dr. Maschka of Prague relates the following case.

A woman, aged fifty-two, was bitten by a dog on the upper lip and forehead. It was not known whether the dog was mad or not. Nine months later, on February 28, 1875, she was admitted into hospital. For three days she had been unable to swallow, and refused food; attempts at deglutition brought on spasmodic attacks. She did not reply to questions; sat with the head bent forward and the eyes half closed, and with a stupid expression of countenance. White clammy saliva escaped from her mouth; the angle of the mouth was frequently drawn downwards, and the head thrown a little backwards. Blowing suddenly in her face produced violent hiccough; the eyelids opened, and the saliva became more copious; the patient, however, could not eject it, but it flowed over the lip. Her voice became inarticulate, and respiration was interrupted.

She lay in bed in a stupid apathetic state. Attempts to make her show her tongue, at once brought on singultus; and if a few drops of liquid were put in her mouth they were rejected along with a large quantity of saliva. The hiccough and increased discharge of saliva sometimes occurred simultaneously, her face at the time having an expression of terror. The pulse was 140; the heart-sounds were normal. Attempts at percussion brought on paroxysms. The pupils were dilated, and were strongly affected by light. The patient died on the day after her admission, and after death the following appearances were observed.

There were no signs of external injury. There was a good deal of blood and serum in the tissues and ventricles of the brain. At the base of the brain, immediately in front of the optic commissure, was

a fluctuating pear-shaped tumour of the size of a filbert, passing for several lines into the right Sylvian fissure. The vesicle had produced a deep impression on the surface of the brain, the substance of which at this part was distinctly reddened and superficially softened. Microscopic examination of the vesicle revealed the existence of a cysticercus.

Dr. Maschka believes that the symptoms observed in this case can be explained by the rapid growth and movements of the cysticercus. [The fact of the patient having been bitten by a dog, however, somewhat complicates the diagnosis.]

A. HENRY, M.D.

WULCKOW ON CANCER OF THE NAVEL.—Dr. Wulckow, of Pirna, reports the following case in no. 39 of the *Berliner Klinische Wochenschrift* (September 27, 1875) because, as he justly remarks, these cases are comparatively rare. Dr. Ernst Kupfer has collected all the cases he can find, amounting to eight, and published them in Langenbeck's *Archiv für Klinische Chirurgie* (Band xvi. Heft i. page 234). The following case is remarkable for occurring simultaneously with one in the stomach.

The patient, a tailor, aged thirty-three, stated that on a dark autumn night in 1872 he suddenly received a violent blow in the stomach; and found, on recovering his senses, that he was hanging over a brick pillar about three feet high. He retired to bed as soon as he could hobble home; but felt severe pains in the injured part for some days. He did not consult a medical man till the spring of 1873. He was then treated for indigestion and gastric catarrh, and ordered to drink saline waters. In the autumn of that year he had a relapse; and again suffered from indigestion, pain in the gastric region, hiccup, and rarely vomiting. About this time his navel 'inflamed,' but painlessly at first. On December 5 his condition was noted as 'strikingly meagre, skin yellowish-white, soft, and flabby. There was slight yellowness of the conjunctivæ. The liver was much enlarged, almost reaching the navel below, and extending far into the left hypochondrium. Within these limits of percussion-dulness were three hard rough bands; the lowermost reached the navel, the highest the pit of the stomach. During inspiration these bands were so movable, that they slipped from the hand which covered them and sank in deeper. On firm pressure, the patient complained of much pain. Cancer of the liver, probably secondary to that of the stomach, was diagnosed. The navel itself slightly overlapped the surrounding skin; it was reddened, and its edges had rough excrescences, which were moist and devoid of epithelium, apparently from friction of a trouser-button. The size of the new growth was about equal to a medium-sized plum, its horizontal diameter being somewhat greater than its vertical. The surrounding skin was puckered and adherent to the new growth by several distinct masses. There was also some infiltration and reddening of the skin just round the navel. By means of the ulnar border of the hand, the whole of the new mass could be separated from the intestines, and it was then pretty certain that it was continuous with the suspensory ligament of the liver. Scrapings of the growth led to the conclusion that it was carcinomatous. Friedreich published the case in no. 1 of the *Berliner Klinische Wochenschrift* for this year, and then the patient was put on decoction of condurango—ob-

tained from Gehre, in Dresden. On March 8, 1874, he died from a rapid succession of severe attacks of hæmatemesis. During the illness great benefits were derived from a suggestion of Dr. W. O. Leube, viz., the use of minced pancreas and meat per rectum—the constant vomiting precluding much feeding in the ordinary way. At the *post mortem* examination, Dr. Felgner found œdema of the lungs and emphysema, fatty kidneys, and extreme anæmia of all the organs. The stomach and intestines were filled with large clots of blood. In the former, near the pylorus, there was a soft new growth, already breaking down, with the microscopic characters of myeloid tissue (*Markschwamm*). The parts contiguous to the stomach were thickened and pigmented, as were the lesser omentum, and the walls of the gall-bladder. This condition was most marked between the greater curvature and the colon. The firm bands felt in life were thickenings of the peritoneum, doubtless from chronic inflammation. The greatly enlarged liver, which was almost bloodless, exhibited only fatty changes. The growth at the navel gave the characteristic giant-cells of an alveolar carcinoma. On a vertical section it resembled the navel transformed, or a bullet with a flattened surface. Its site, as regards the tissues, was the layer of new-formed cells in the subcutaneous areolar tissue; the epidermis and rete Malpighii were quite free from it. It was not possible to prove an extension of the growth to the suspensory ligament of the liver. The co-existence and simultaneous occurrence of two separate malignant growths in different tissues, both apparently due to the same accident, is worthy of note. Admirers of condurango may not unreasonably explain its failure in this case, by the fact that it was not employed until the disease had advanced too far to allow of any hope of cure.

MEDICINE.

WOOD ON PARAPLEGIA.—The eleventh of the series of 'Clinical Lectures by American Physicians,' edited by Dr. Seguin, is by Dr. H. C. Wood, jun., On the Diagnosis of Diseases, accompanied with real or apparent Paraplegia without marked muscular degeneration.

After warning students and others against the pseudo-paraplegia due to inflamed joints, injuries, etc., the author first speaks of cerebral paraplegia, due to disease on both sides of the brain, as exceedingly rare. He then divides the spinal cord into three pathological regions; the posterior columns, the grey matter, and the antero-lateral columns. Disease of the *posterior columns* produces loss of co-ordination of muscles (from destruction of the longitudinal commissural fibres), and either pain

with hyperæsthesia, or complete anæsthesia, according to the completeness of the process. Destruction of the *grey matter* produces anæsthesia, while in the earlier irritative stages the reflex functions of the cord are exaggerated, with little or no pain. If the anterior cornua are affected the muscles waste. Disease of the *antero-lateral columns* is recognised by loss of movement, without pain or loss of sensation.

Affections of the spinal *membranes* act, not directly upon the cord by the pia mater, but by pressure on the roots of the nerves as they pass through their meningeal sheaths. The symptoms are pain and spasm: sensation is usually to some extent blunted, but motion is not lost until the latest stages of the disease.

Dr. Wood next considers the diagnosis between organic disease of the cord in general, and functional conditions which lead to more or less marked paraplegia, dividing the latter into anæmia, reflex irritation, dyscrasia, and hysteria. *Paraplegia due to anæmia of the cord* is, he thinks, observed, not only after severe hæmorrhage, but also from other exhausting discharges, and a case is quoted which occurred immediately after an attack of cholera. It is characterised by the loss of motion, and sensation being only partial, and by the bladder remaining unaffected; but Dr. Wood admits that diagnosis between this condition and slight congestion of the cord is impossible, except as an inference from preceding hæmorrhage. *Reflex paraplegia* is recognised as a purely functional result of irritation of the urino-genital organs, as from calculus in the kidney or bladder in men, from adherent prepuce in boys, and from uterine tumours in women. *Paraplegia due to dyscrasia* refers to the palsies which sometimes follow diphtheria, etc. In all these varieties paralysis is gradual in its onset, in *hysterical paraplegia* it is always abrupt, in that due to organic disease it may be either, but here pain or spasm are generally present, which are absent in hysterical and other functional palsies. Complete anæsthesia, again, is very rare except in organic disease or hysteria. The well-known feeling of 'a cord round the waist' is considered by Dr. Wood to be characteristic of organic disease; and equally so the retardation of sensory impulses which produces a distinct interval between the patient's seeing his feet touch the floor and feeling it. Reflex action is excited in organic, not in functional paraplegia. Paralysis of the bladder may complicate hysterical paraplegia; but, when hysteria is out of the question, urinary symptoms are diagnostic of organic disease of the cord. If the palsy have suddenly ceased for a time, it is almost certainly hysterical; and although it is not true that electro-sensibility is always lost in hysterical paraplegia, while electro-contractility remains, yet insensibility to a strong faradic current, while the muscles are contracting, is an argument in favour of hysteria.

Passing next to the diagnosis between forms of organic paraplegia, the author discusses our means of distinguishing whether the affection be primary in the cord, or *secondary to disease of the spine*. Rosenthal's test of passing a pair of faradic electrodes down the back on each side of the vertebrae is useful here. There may be some pain produced when the bone is unaffected; but if a current 'of some power' produce no local pain, we may conclude that there is no caries or other disease of the spine.

Next may be separated off those cases of paraplegia due to organic disease of the cord, which are accompanied by rapid wasting of the muscles, and loss of galvanic irritability; such are cases of Cruveilhier's palsy (*progressive muscular atrophy*) and *infantile palsy* (the essential paralysis of children).

Dr. Wood proceeds to divide the remaining organic paraplegiæ into those characterised by rapid, and those by slow onset. The former include hæmorrhage into the cord or its membranes (spinal apoplexy), congestion of the cord, and acute myelitis. Simple *congestion* produces sudden and uniform bilateral paralysis of motion, sensation and reflex function, without pain, spasms, or constitutional disturbance.

[That the power of motion is much more affected than that of sensation, is ascribed by Ollivier to the greater distance of the posterior than of the anterior columns from the vertebrae, and by Dr. Wood to the sensory fibres running deeper in the cord than the motor; but it must be remembered that in hemiplegia also sensation is usually less affected than movement and more rapidly recovered.]

Hæmorrhage into the substance of the cord produces absolutely sudden and complete paraplegia with increase of reflex activity (from removal of inhibition), but without fever, pain, or spasm. If pain and spasm are present, the hæmorrhage may be supposed to be meningeal (a good case of meningeal apoplexy, with gradual onset of symptoms, is given). If the temperature is raised, the above symptoms point to *acute myelitis*, which is, however, confessedly difficult to diagnose from spinal meningitis. Dr. Wood thinks that pain and spasm are more severe in the latter; but doubtless the two are often combined.

Passing to paraplegia of gradual onset dependent on organic disease of the cord, the first group separated by the author is that of paralysis due to tumours, or to curvature of the spine. Next come cases in which tremors are absent, including true non-inflammatory '*white softening*,' a very rare disease, and almost indistinguishable from *chronic myelitis*, and the various forms of the latter. Those recognised by the author are chronic myelitis due to sexual excesses, which is probably curable in its early stages, chronic myelitis with softening, and chronic myelitis with hardening of the cord. Chronic inflammatory softening usually affects the whole cord, and is gradual in its onset. Chronic inflammatory induration (*sclerosis*, chronic interstitial myelitis) rarely affects the whole thickness of the cord at once, and may, therefore, be subdivided by its local distribution. When the seat of the disease is in the *posterior columns*, there result the well-known symptoms of locomotor ataxia. The author believes that pain is very rarely, if ever, absent in this malady, and gives the usual caution against confounding it with ordinary neuralgia, or with so-called rheumatism. He well describes the rapidity, severity, and intermission of these pains, and confirms Charcot's observation that they may affect not only the limbs but the rectum, bladder, or stomach. When a supposed sciatica affects both legs, and has no points of greatest intensity, when, instead of local tenderness in the painful part, there is concomitant anæsthesia, and when the early pains are relieved by long intervals, the disease may be safely regarded as *tabes dorsalis*. Beside the 'spinal' symptoms of ataxia, there are not unfrequently affections of the third, sixth, optic or other cranial

nerves, with diplopia, amaurosis, and optic neuritis, or colour-blindness. [Hence ataxia was described by Gull as 'cerebral paraplegia.']

When the *anterior columns* of the cord are affected by sclerosis or grey degeneration, spasms and heightened reflex activity are the first symptoms, without pain or anæsthesia, and these are succeeded by complete motor paralysis.

Probably the cases of so-called 'spinal epilepsy' of Brown-Séquard (named tetanoid pseudo-paraplegia by Dr. Seguin), are only varieties of ordinary paraplegia, in which the reflex functions of the cord are remarkably active, from cutting off of cerebral inhibition together with irritation of the central grey matter; they may depend on curvature of the spine, tumour, or myelitis as the anatomical cause.

There remain, however, as distinct chronic forms of paraplegia, 'paralysis agitans' and 'multiple (insular) sclerosis.' In the former obscure affection the loss of power in the lower limbs is probably dependent on their shaking; in the latter, the tremors only occur during movement. In both, the lesions are often confined to the cord, but may extend to the pons or to the cerebrum.

[There are some curious Americanisms in this lecture, as 'compromit,' 'the crazy bone,' 'waked up,' 'trunkal pains,' 'a clergyman of some prominence'; words like 'pons varollii' and 'dischromaptosis' occur; and 'in concluding this bird's-eye view of spinal diseases,' the author thinks he 'may be allowed to express the desire that it may prove a useful skeleton.'—*Rep.*]

P. H. PYE-SMITH, M.D.

ERB ON ACUTE SPINAL PARALYSIS IN ADULTS, AND ON OTHER ALLIED DISEASES.—Dr. W. Erb, of Heidelberg, has a paper on this subject in the *Archiv für Psychiatrie*, Band v. Heft 3.

Since Heine's classical work, 'spinal infantile paralysis' has been an acknowledged pathological condition of the nervous system, and so exact was his description that subsequent investigation has only added some particulars concerning the relation of the galvanic current to the affected nerves and muscles. The main features are 'sudden commencement with acute cerebral symptoms and, as a rule, fever, deafness, delirium, convulsions; early development of a more or less complete paralysis spreading over the trunk and extremities, absence of any lesion of sensibility, of paralysis of the sphincters, and of bed-sores, gradual improvement, but very unsymmetrical restoration of movements, which in part are lost for ever; great atrophy, coldness and blueness of the paralysed extremities; diminution and loss of faradic excitability, arrest of growth of the bones, numerous and extensive deformities resulting from the paralysis.'

But milder cases are seen, beginning much in the same way, often running a milder course, and terminating after months or years in complete restoration of the movements. Such are the cases of 'temporary spinal paralysis' of Kennedy, Frey, and others. There may be all possible grades of severity, from the slightest, affecting one extremity or one group of muscles, to the most severe, where several groups are involved and the atrophy and paralysis are persistent. Although in the 'temporary' form restitution follows more quickly and completely, there is no doubt that all forms must be viewed as modifications of the same disease. At first the disease was thought to be one exclusively belonging to the age of child-

hood, but Duchenne de Boulogne proved its occurrence in adults from eighteen to forty-five years old; and his clinical account of symptoms is exactly the same as in children, and other observers have corroborated this. Concerning the production of the temporary form in adults, Duchenne does not speak with much certainty, for the cases given by him are of so recent a date that the termination cannot be surely told.

Later pathological investigations of the permanent form of acute spinal paralysis are very important and conclusive. Heine, from consideration of the symptoms, concluded that the disease was of spinal origin. Lockhart Clarke, Charcot, and others have proved beyond doubt that in every case there is an alteration of the grey anterior horns, acute in its nature and attended with atrophy of the large ganglion-cells and consecutive myelitis; and Gombault has recently shown the same pathological change in the analogous adult affection. It is disputed whether we have to do with a primary degeneration and atrophy of the ganglion-cells (as the French hold) or with an acute interstitial myelitis which causes the injury to the ganglion-cells, but the latter would seem the more correct judged from the changes in the vessels, the numerous granule-cells, the increase of connective tissue, etc.

However caused, the change may be described as an inflammatory one, leading on to atrophy and degeneration, and hence Kussmaul's term 'acute anterior poliomyelitis' may be accepted. The facts now determined throw unexpected light on many hitherto incomprehensible forms of disease. Thus they have led Duchenne de Boulogne to a more precise note of the disease named in his latest edition 'subacute general anterior spinal palsy,' meaning by it a paralysis which develops without fever gradually (in the course of weeks and months), usually attacking the lower extremities before the upper, sometimes proceeding in the opposite direction, very often attacking the respiratory muscles and those of speech and deglutition, leading to death as a rule, but at times becoming stationary, or leading to recovery. There are considerable atrophy *en masse* of the paralysed muscles, diminution and loss of faradic excitability, absence of affection of sensibility and of the rectum and bladder, and no bed-sores.

Frey (*Berliner Klinische Wochenschrift*, 1874, no. 44) gives a good case of this kind, to be distinguished from progressive muscular atrophy, in a girl seventeen years old. However striking these pathological appearances may be, it must be remembered that in the anterior half of the cord there are, besides the grey substance, other structures belonging to the motor system, disease of which may lead to this complex series of symptoms.

An especially promising department in the localization of distinct centres of disease in the cord is found in the so-called 'acute ascending palsy.' There is no doubt that in this group of diseases, chiefly based on the gradually ascending and fatal termination, a number of different forms have been combined, just as the most different disorders used to be named 'paraplegia.' In 'ascending paralysis' many clinically different diseases are included. There are cases, some of which begin with, others without, feverish symptoms; some with, others without brain-lesions; some with lesions of sensation and bladder-affection, others without; at one time atrophy with lessening of electric excitability, at another both absent; now a rapidly fatal end,

then recovery. When among such cases a differential diagnosis is carefully made, it will be seen that a distinct class can be included under 'anterior poliomyelitis.' Eisenlohr reported a case of this kind. A strong man, aged thirty-three years, had acute feverish symptoms, pain and progressive weakness of the legs, which in six days increased to paresis, attacking also the arms, and attaining its maximum in two or three days. Sensibility and the action of the bladder and rectum were normal; there were no bed-sores; reflex excitability was increased; there was no cerebral lesion. Improvement began on the twelfth day of the disease, and recovery ensued in two months. At no time was there atrophy of the paralysed muscles. The symptoms point to poliomyelitis, but it looks as if this inflammatory affection of the grey matter may be so slight and brief that no atrophy results. Again, there may be diseases exactly alike clinically, in which, though the place of the disease is the same, the lesion is different. We cannot at present say that the white columns were not the affected, if not, the principal seat of disease.

Some good remarks are made on the presence of electrical reaction, due to degeneration of fibre as a diagnostic element in these various spinal diseases (*Entartungsreaction*.) T. CLAYE SHAW, M.D.

GUENEAU DE MUSSY ON AUSCULTATORY PERCUSSION.—No. 57 of *La France Médicale* (July 17, 1875) contains an article, by Dr. Noel Gueneau de Mussy, on combined auscultation and percussion in its application to the diagnosis of thoracic diseases. Originally an American proposal, this method of exploration, which has proved so useful in the diagnosis of abdominal tumours, was warmly advocated by Trousseau as a means of recognising pneumothorax: for in cases where the pneumothorax has no communication with the bronchi on percussing the front of the chest, over the sternum, whilst we auscultate the back of the chest, we get a brassy or metallic sound, called by Trousseau *bruit d'airain*. In such cases, metallic tinkling and amphoric cough would be absent; and almost the only physical sign, except the one mentioned above, would be the entire absence of vesicular respiration. It is, therefore, a valuable sign in pneumothorax. In the healthy chest, if we listen with the ear (or a stethoscope) in the anterior region, whilst percussion is made over the dorsal or lumbar apophyses of the vertebræ, we get a metallic vibrating sound, the echo of our percussion, which much resembles the cracked-pot sound. Any alteration in the density or permeability of the lung-tissue, or in the tension of the air which distends it, modifies this consonance; and instead of being vibrating and metallic, it becomes more feeble and duller, whilst occasionally its pitch is raised. In this way, M. Gueneau de Mussy thinks that some central consolidations of the lungs can be better diagnosed than by direct percussion or auscultation. For these purposes, however, it is only available in the upper regions of the chest. In the lower, the heart on one side, the liver on the other, interfere with the vibrations. It is possible, in this way, to make out the upper convex border of the liver better than by any other means. Lately it was in this way that he first discovered that the heart had just been pushed forcibly over to the right side, in a case of extensive effusion into the left pleural cavity in a young female. In an old lady whose dyspnoea was disproportionate to the physical signs, percussion of

the sternum, with auscultation behind, led to the diagnosis of central consolidation of the lung. Of course the ear must be at the level of the consolidation to catch the dull, flat, non-vibrating sound given by it to the percussion waves. To explain the phenomena he adopts the theory of consonance. Emphysema, being often accompanied with considerable tension in the chest, renders this sound dull and less vibrating. So do deposits of tubercle. In cavities of large size, the sound is often much raised in pitch. Rarely we get a cracked-pot sound, and occasionally the vibrations are not much affected. The percussion should be made on the bare skin. Except in the cases mentioned, M. Gueneau de Mussy has not found any striking results from this method of examination.

W. BATHURST WOODMAN.

FRÄNKEL ON THE ELIMINATION OF NITROGEN BY THE KIDNEYS.—Dr. A. Fränkel, assistant to Professor Traube, in Berlin, writes an interesting article on his investigations on the elimination of nitrogen, in nos. 43 and 44 of the *Berliner Klinische Wochenschrift*, 1875. Briefly, his account is as follows.

K. H., a mason, aged forty-nine, was admitted into the Charité Hospital on April 8, 1875. He dated his symptoms most definitely from a chill in the previous October. In December, 1874, he noticed oedema of his feet. On admission, there was moderate oedema of feet, legs, and loins. The mucous membrane appeared normal, and his appetite and digestion were good. There were considerable tension in the radial arteries, and signs of cardiac hypertrophy. There was moderate ascites; no enlargement of the liver or spleen. Pressure over the region of the kidneys gave pain. The urine was yellow, slightly turbid, without sediment, and contained a large amount of albumen. The residue on the filter, when examined with the microscope, showed a large number of compound granule-cells (exudation corpuscles) with detritus, with numerous finely granular fatty casts and many leucocytes, or lymph-corpuscles, which had undergone fatty degeneration. No blood-discs were present. The quantity of urine was said to be less than formerly. As regards the progress of the case, it may be divided into stages. 1. The treatment during the first five days was purely expectant, but the quantity of urine increased to 2,280 cubic centimètres (about eighty ounces). The oedema nearly disappeared; but the albumen and casts, etc., remained as before. 2. From April 14 till May 10 the oedema increased, although the urine reached 2,450 cubic centimètres (nearly eighty-eight ounces) in twenty-four hours, with a specific gravity of 1015. From April 18, the quantity of urine gradually decreased to 1,000 cubic centimètres (about thirty-four ounces) or less, whilst its specific gravity rose. The albumen was still present in large quantities; the other solids were a little less. He was taking compound infusion of senna, and had frequent evacuations from the bowels (as many as six a-day). 3. From May 10 he had lukewarm baths on alternate days, and was packed in blankets afterwards. This removed the dropsy by the 23rd of that month, though the diuresis was lessened. The lowest quantity of urine passed was 650 cubic centimètres (little more than a pint) in the twenty-four hours, with specific gravity 1030. The average of twenty-four hours in this period was 840 cubic centimètres (nearly a pint and a-half), with specific gravity of 1029. 4. From May 31 the baths were discontinued, the dropsy in-

creased, and the urine continued lessened as before.* As regards the chemistry of the urine, many estimations of the urea in it were made, and it occurred to Fränkel that it would be well to estimate, as far as possible, the nitrogen taken as food, and the nitrogen excreted. Bischoff and Voit have shown that when a man or an animal is long kept on the same food, as to quantity and quality, a condition soon sets in, of 'equivalency of nitrogen,' in which just as much nitrogen is found in the urine and fæces as is taken in in the food; provided, of course, that the food is sufficient and proper of its kind, and not so excessive as to demand much intestinal or post-gastric digestion. This man's digestion appeared very good, and his bowels were regular. Dr. Fränkel therefore considered that the fæces might safely be left out of the calculation. He accordingly put him, from May 31 to June 12, on the diet No. III. of the hospital, equal to three portions of broth, and two of bread, with the addition of a piece of roast meat, two eggs, and two glasses of milk in the twenty-four hours. The nitrogen contained in this was calculated at 11.62 grammes, equal to 24.9 grammes of urea. Leaving out the first and last days for greater correctness, the following table shows the urea obtained in five consecutive days.

Date	Quantity of urine in cubic centimetres.	Specific gravity.	Urea in grammes.
June 4	2650	1012	25.44
" 5	2160	1013	23.76
" 6	2670	1013	27.50
" 7	3280	1010	25.58
" 8	2450	1012	22.66

or a mean of 24.99 grammes per diem, which equals 385.63 grains—the average quantity of urine passed equalling eighty ounces nearly, with an average specific gravity of 1012. The chlorides were precipitated previously by silver nitrate. The urea varied within the limits of five grammes daily, probably from slight variations in nitrogen value of diet. As albumen was also present in large quantity, Dr. Fränkel was not satisfied with the estimation of urea by Liebig's method, but made estimations of the total nitrogen with soda-lime in a combustion-tube. He also tried the urine of two convalescents with a similar diet, and found the amount of urea nearly the same.

From April 15 to May 26, on fifteen days, the urine of this patient was freed from albumen, and the mean of the twenty-four hours on these days was 21.87 grammes, equal to 337.67 grains (the maximum being 28.26 grammes, the minimum 19.2 grammes). [An elaborate table of twelve other urea and nitrogen estimations is given, but the context is by no means clear as to which of the patients is referred to in these analyses. As, however, the means are 22.32 grammes of urea, or 10.38 nitrogen, by Liebig's method, whilst the total nitrogen found by combustion was 11.38, equal to 24.38 grammes (376.72 grains) of urea, it will be perceived that there was a very close correspondence in any case.] Fränkel's commentary is briefly as follows. 1. We have here a pure, uncomplicated case of diffuse nephritis, in the second stage (of Traube, etc.), or in other words, in the fatty stage. The cardiac and vascular states are considered as direct consequences of the renal affection. 2. The noteworthy peculiarities are (a) the early diminution of the amount of urine; (b) the fact that the

patient passed in twelve days, from May 31 to June 12, an average daily quantity of 22.32 grammes of urea (in each twenty-four hours). If we pick out five days of those in which the total nitrogen eliminated was calculated, we find their amount to be 22.18 grammes of urea, but the total nitrogen amounted to 11.62 grammes or, calculated in urea, 24.9 grammes, equal to 376.7 grains, or about equal to the nitrogen ingested. It would therefore appear that enough of his kidney-tissue remained physiologically competent, in spite of the grave disease of the rest. 3. The process of elimination, so far as performed by the healthy parts of the kidney, may be termed compensatory. Like cases in which one kidney is extirpated, or, for example, a dog weighing from sixty-six to eighty-eight pounds will, on the fifth or sixth day of fasting, excrete about 185 grains of urea; but if he be fed on lean meat of about five and a-half pounds weight, he will pass the enormous quantity of 2,810 grains of urea day by day!

Fränkel concludes, therefore, that diffuse nephritis, with much albumen in the urine, is not necessarily connected with diminished excretion of urea and other nitrogenised products; since much of the kidney may remain functionally healthy and compensate the rest. These are the cases which will throw light on renal pathology, if only careful analyses are made. [This very valuable paper of Fränkel's is somewhat impaired by a want of clearness and want of correspondence between the tables and the statements in the text. The man's weight is omitted; and if eighty ounces of urine is to be considered a small quantity for twenty-four hours, we should surely have had some data as to Fränkel's estimate of the normal quantity of urine.—*Rep.*]

SCOLOSUBOFF ON ARSENICAL PARALYSIS. — No. 25, vol. ii. of the *Thermes de Dax*, states that M. Scolosuboff, physician to the Moscow hospital, has frequently noticed arsenical paralysis in workmen. The extremities are most affected, fingers and toes, hands and feet. The parts attacked present the following characters: 1. Atrophy of muscles, with loss or diminution of contractility under the influence of electric currents; 2. Altered sensibility; 3. Lowering of the temperature, alteration of the colour of the skin and œdema. Dr. Scolosuboff has made experiments on dogs with arsenite of sodium, mixed with their food, or subcutaneously injected. In chronic poisoning he has found that arsenic accumulates in the nervous centres, where it exists in quantities thirty-six or thirty-seven times greater than in the muscles of the same animal. In acute poisoning the arsenic can sometimes only be found in the brain. He therefore concludes that in arsenical poisoning, the medical jurist ought specially to investigate the nervous centres, since the arsenic accumulates in these. As regards the Moscow workmen, he supposes that the arsenic first attacked the brain and spinal cord, and that the affections of the extremities were dependent on the lesions of these centres. W. BATHURST WOODMAN.

FERRIER ON LABYRINTHINE VERTIGO—ME-NIÈRE'S DISEASE.—Dr. Ferrier (*West Riding Asylum Medical Reports*) describes a typical case of this disease. The patient, aged thirty, a member of the medical profession, consulted Dr. Ferrier in reference to certain distressing symptoms, which briefly may be enumerated as giddiness, faintness, a feeling as if being whirled to the left, and a buzzing and ringing noise in the left ear. On otoscopic exami-

* This statement seems inconsistent with the figures in the tables. It probably refers to the man's own account of his former habits.—*Rep.*

nation, the left auditory meatus was found to be somewhat congested and catarrhal, but was not stopped up, nor was there any discharge. The membrana tympani was also congested. The sense of hearing as regards the aerial vibrations of the tuning-fork and to musical notes was unimpaired, and even more acute in the left ear than in the right. There was, however, complete insensibility in the left ear to the vibrations of the tuning-fork placed on the bridge of the nose, or on any part of the skull. These were only perceptible on the right side, in whatever position the tuning-fork was placed.

[A most able and lucid discussion of this disease follows the report of the case, which is of such importance that we can only recommend our readers to peruse it for themselves, as the whole paper is worthy of the deepest consideration.—*Rep.*]

Touching upon the physiology of the labyrinth, Dr. Ferrier tells us that the membranous canals are supplied with nerves only at their ampullary dilatation. These canals being filled with fluid, it is easy to see that variation in the position of the head will cause different degrees of tension or pressure on the respective ampullæ, and hence impressions on the ampullary nerves may be generated in this manner apart from any impression originating from without. If we suppose that the head is perfectly still, then the labyrinthine impressions are in a state of statical equilibrium. A movement of the head to one side or the other will alter these conditions. A sudden deviation of the head will cause simultaneously a plus and minus variation in opposite ampullæ, variations which call forth adapted movements of equilibration. Hence we can understand that the balance will be overthrown if one of the forces is withdrawn or abnormally altered. The perturbation of equilibrium will be in the direction of the unopposed or predominating force.

Applying the experimental data obtained by Flourens and Crum-Brown to the pathology of Menière's disease, Dr. Ferrier goes on to say that the characteristic symptoms of the disease are—that the patient is suddenly seized with vertigo and a feeling of nausea or positive sickness, with great constitutional depression and faintness. Usually the giddiness comes on simultaneously with ringing or buzzing in one, or it may be in both ears; and generally in the ear principally affected more or less deafness is found to exist, which ultimately becomes absolute.

Contrasting the conditions of negation and irritation of the semicircular canals, Dr. Ferrier writes that, from the researches of Flourens, it would seem that negation of the horizontal canal on one side causes the body to be thrown or spun towards the same side, and that negation of the superior canals causes the body to be thrown forwards, and a like negation of the posterior canals causes the body to be thrown backwards. We should, therefore, expect that if the lesion were an irritative one the phenomena would be reversed; and that, therefore, irritation of the left horizontal canal should cause a feeling of rotation to the right side, and *vice versa* in the case of irritation of the right; and similarly, a feeling of being hurled forwards or backwards according as the irritation affected the posterior or superior canals respectively.

Next, in regard to the feeling of giddiness or vertigo: disturbances of equilibrium do not necessarily create a feeling of vertigo; and, as Hughlings Jackson justly remarks, it is erroneous to say that

the feeling of vertigo is the cause of the reeling. Vertigo is rather the subjective side of perturbed or incongruent sensori-motor co-ordination. In Menière's disease it is chiefly the incongruence between labyrinthine and visual impressions which causes the feeling of giddiness. When the body is rotated round on a revolving disc, there is no feeling of giddiness so long as the eyes are shut, as Crum-Brown has shown. If the eyes be opened, however, either during the primary rotation or during the sense of complementary rotation after the disc has ceased to revolve, a feeling of giddiness at once comes on. External objects seem to be revolving also, and this causes a feeling of insecurity or giddiness, and giddiness is also felt if external objects turn round, though the individual does not. Labyrinthine impressions are correlated with ocular movements in the co-ordinating centres, and Flourens' experiments show that the oscillation of the eyeballs occurred when the semicircular canals were injured. This is a fact of considerable importance in reference to the mechanism of central co-ordination, and the condition of the eyeballs in attacks of Menière's disease would be well worthy of study.

The next most prominent symptom of Menière's disease is the nausea or sickness, with its accompanying systemic depression. Czermak found that section of the semicircular canals in pigeons caused not only the disturbances of equilibrium and agitation of the eyeballs described by Flourens, but also very frequently nausea and vomiting. Here, therefore, we have another point of similarity between Menière's disease and experimental lesion of the semicircular canals in animals.

The last symptom of note in Menière's disease is the local condition of the ear, and particularly as regards hearing. There is frequently pain, which is intensified by sound, in the region of the affected ear. This is quite in accordance with Flourens' results. He found that injury to the semicircular canals caused manifest signs of pain, and that sounds seemed to cause painful sensation. Hearing is progressively abolished in the ear affected with the lesion, which gives rise to the special symptoms of labyrinthine vertigo. As injury to the semicircular canals did not abolish the sense of hearing in Flourens' experiments, but as it was abolished by destruction of the cochlea, we must conclude that when, in the progress of Menière's disease, deafness ensues, the lesion has extended into the cochlea.

The subjective sensations of whizzing, ringing, &c., in the affected ear will coincide with a stage of abnormal irritation preceding total annihilation of the function of the auditory nerve.

Dr. Ferrier concludes by saying that, should the above observations be confirmed, they will serve to show that the semicircular canals are, as regards hearing, specially concerned in the reception and transmission of skull vibrations in contradistinction to aerial vibrations.

H. SUTHERLAND, M.D.

ELLIS ON THE CAPILLARY BRONCHITIS OF ADULTS.—Dr. Colvin Ellis (*Series of American Clinical Lectures*, edited by E. Seguin, M.D., No. VII.) devotes a clinical lecture to capillary bronchitis in adults, and the frequency of its complication with changes in the air-vesicles, or parenchyma of the lungs, and its relation to catarrhal pneumonia. He shows that the line between capillary bronchitis and catarrhal pneumonia is

too sharply drawn; and the complications of the former often entirely unnoticed, or obscurely hinted at. The lecture is founded upon five cases, three of which exhibited the symptoms and physical signs announced to be indicative of capillary bronchitis; with the addition of dullness on percussion over certain regions of the chest. One of these ended fatally, and *post mortem* examination showed consolidation of those parts of the lung where deficient resonance was detected during life; they were dense, distended, non-crepitant, covered especially with false membrane, and exhibited several distinct forms of morbid change. The lower portions of the lungs were in a state of pale grey translucent infiltration, with exceedingly minute yellow opaque points, apparently due to fatty degeneration of the alveolar contents, and large yellow opaque spots and lines, suggesting bronchial canals. The upper border of this infiltrated portion presented small patches, the size of beans, dotted with yellow, containing in their centres bronchi, with more or less purulent matter. Both large and small bronchi contained purulent secretion. Microscopic examination of these sections of the hardened lung showed alterations characteristic of croupous, catarrhal, desquamative, and interstitial pneumonia, the latter more especially of a chronic character. The two remaining cases differed somewhat from the rest. One was comparatively slight, the physical signs being limited to subcrepitant râles over the right upper lobe only, without impairment of resonance on percussion. The last example exhibited the symptoms of acute pulmonary consumption, and the *post mortem* examination revealed extensive infiltration of both lungs with cheesy material, and vomicae. In addition there were nodules and granules, grey and opaque, of the size of a pin's head; many of which, particularly the larger, presented the appearance of peribronchitis, while the smaller might have been miliary tubercles. In the kidneys were yellow nodules, and in the liver miliary tubercles. After discussing the various and somewhat conflicting descriptions of capillary bronchitis given by leading authorities, the author contends that the frequency with which the inflammation involves the air-vesicles and gradually causes consolidation of the lung, is not generally stated with sufficient distinctness. So much stress has been laid upon resonance, that dullness is supposed to exclude the disease, while it is only the evidence of a very common accompaniment both in cases where the infection is general and in those where it occupies only a limited portion of lung. The changes which these consolidated portions of lung undergo may be traced until they end in the destruction of the lung-tissue, and the process may be repeated in one portion of the lung after another. The subcrepitant râles of capillary bronchitis may be mingled with the fine dry crepitant râles which indicate an affection of the air-cells, and which differ in no way from those heard in ordinary croupous pneumonia. In some cases the symptoms and physical signs are those of ordinary pneumonia, but dullness and subcrepitant râles persist, and the patient sinks with diseased portions of lung, partly caseous, partly destroyed. The statement of Jürgensen that catarrhal pneumonia never begins in the air-vesicles, is not to be accepted absolutely. Cases are met with in which the first physical sign is the dry crepitant râle of vesicular inflammation, followed after a time by the moist subcrepitant râle of the bronchioles. It would be impossible to show that

the inflammation did not begin in the small bronchi, but the evidence of such beginning is wanting.

[These observations have an important bearing upon the question of the inflammatory origin of phthisis. One great difficulty in the way of the acceptance of the views of Virchow and Niemeyer—that most so-called tubercles in the lungs are primarily of inflammatory origin—lies in the fact that the physical signs by which such catarrhal-pneumonic changes ought to be betrayed are not met with clinically as common antecedents of pulmonary tubercular phthisis. The physical signs of limited pneumonia in combination with capillary bronchitis are frequently encountered in young children, but they are rarely met with between puberty and full adult life—the time when pulmonary phthisis is usually developed. If simple broncho-pneumonia does constantly occur at this time, and is the starting-point of most cases of so-called tubercular consumption, its existence has been overlooked; but this may be due to the neglect of sufficiently minute physical examination of the chest in cases presenting, perhaps, merely general symptoms of slight bronchitis or catarrh.—*Rep.*] W. B. CHEADLE, M.D.

EWALD ON THORACENTESIS.—Dr. Ewald has a paper on this subject in the *Charité Annalen* for 1874 (Berlin, 1876), in which he gives statistics of forty-six cases of pleuritic effusion, twenty-six of which were incised, including three cases of empyema. Of these seven died, six recovered, and twelve were improved by the operation; nine were punctured, with the result of seven deaths and two improved; and eleven underwent no operation, with seven deaths, three recoveries, and one improved. The incisions were made freely without antiseptic precautions, but various antiseptic lotions were used in the after-treatment; puncture was made with disinfected instruments and exclusion of air. In the incised cases none had any increase of fever after the operation, though one died of collapse after four hours; of those punctured, four had increase of fever and one died of collapse sixteen hours afterwards, but in both cases there were complications. As the result of his experience he formulates the following rules.

1. Serous effusions should not be punctured before the third week except to avert imminent death. Puncture in the third or fourth week is most favourable as to mortality and prognosis.
2. If *puncture* be made with exclusion of air and disinfected instruments, no serous effusion will putrefy.
3. It must be proved by exploratory puncture whether a pleurisy is purulent or serous.
4. Purulent pleurisy should be incised as early as possible, and not punctured.
5. The mortality after incision for empyema is between 50 and 60 per cent.
6. Bloody exudations in his cases have been always caused by malignant new formations in the pleura.
7. Serous exudation does not exclude the existence of tuberculosis or cancer of the pleura.

SURGERY.

SEMPLE ON SPIDER-BITES.—In a paper in the *Virginia Medical Monthly* for December, Dr. G. W. Semple describes the following cases of spider-bite which have occurred in his practice during forty years.

Case I.—September 4, 1853. I was called to see Mr. D., who had been bitten by a small black spider on the prepuce, whilst on the privy seat, at half-past twelve o'clock. The bite at first caused only itching of the prepuce, with a little redness of the part, but in less than half an hour nausea, followed by severe abdominal pains, ensued. A messenger was despatched in haste on horseback for me, three miles off. Before I reached the patient at half-past two o'clock, violent præcordial pains extending to the axilla, and down the arm and forearm to the fingers, with numbness of the extremity, had succeeded, attended by apnoea. In consequence of the violence of the symptoms, Dr. Stineca, surgeon of the post, had been sent for, who had given two doses of laudanum of a drachm each, and two of rectified whisky of two ounces each; and, being in ill health and unable to remain, had ordered his hospital steward to apply four dry cups over the præcordia. This had just been done when I arrived. I saw the blood, thin and florid, fill the cups like water oozing through muslin. When the cups were removed, the blood, emptied into a basin, did not coagulate; and blood continued to ooze slightly from the surfaces to which the cups had been applied until the next morning, though a solution of tannin was applied. I found the patient suffering extremely from the most violent præcordial pains and from apnoea, and also violent pain in the left arm, which was almost paralysed. His pulse was 130 and very feeble, his skin cold as marble, and his countenance expressive

of the deep anxiety he felt and expressed in words. The laudanum and whisky seemed to have produced no effect—the nausea and abdominal pains having subsided before they were administered. There was no pain, inflammation, or swelling where the bite was received. Even the itching of the part had subsided. I gave the patient every half hour for several hours a drachm of aromatic spirits of ammonia, and as much whisky and water as he could be induced to take, and afterwards gave them every hour; also pediluvia of hot mustard and water, frequently repeated, until the next night.

8 A.M.—The symptoms continued unabated; indeed, the patient grew worse until half-past two o'clock, twenty-six hours after he was bitten, for his pulse had then become so frequent that it could not be counted, and so feeble that it could scarcely be felt. He then vomited black vomit copiously—a quart or more. Soon afterwards reaction set in, his pulse gradually regained force and became less frequent, the pain subsided, and the respiration improved. At 8 P.M. the pulse had gained considerable force, and the patient slept until some minutes after 12, when he awoke; his pulse was pretty full at 1.10; his surface warm and perspirable, and he felt almost free of pain. After a short interval he again fell asleep, and slept quietly until morning, when he awoke—his respiration healthy, pulse 80, regular and with sufficient force, and entirely relieved of pain. He soon afterwards had two pretty copious evacuations from the bowels, similar to the black vomit he had vomited. After this, he said he felt quite well, and took a light breakfast and dinner, and returned that evening to his residence in Portsmouth, and in a few days went to work at his trade. In thirty-six hours from the time he was bitten, he took about three quarts of the best rectified whisky, without showing the least symptom of intoxication.

Case II.—I report from memory. About June 20, 1861, on a scout with a party of cavalymen under command of Major Hood (afterwards Gen. Hood), in a wood about four miles north-west of Newport's News, a man belonging to Captain Goode's (Mecklenburg) troop, about 3 A.M., just as the order to saddle was given, cried out that he was bitten by a spider, and called for me. He was bitten in the groin, and complained of only a slight pricking and itching at the spot where he was bitten, but was complaining of severe abdominal pain, with nausea, and a sinking sensation at the epigastrium; and his pulse, in a few moments after the bite, had already become quick and thready, and the skin very cold. I immediately commenced the administration of aromatic spirits of ammonia and whisky, as in the other case. He was moved on horseback with the party about a mile and a half, a good pallet of blankets was made for him in a thick shade, and he was rendered as comfortable as possible. The symptoms followed the same course as in the first case, but amendment commenced about 12 M., when all my supply of whisky—one and a half quart bottles of the best of my own private store—and all the supply of spirits of ammonia, were exhausted; but the commencing reaction was sustained by a pint of whisky procured (the last he had) from a friend of mine hard by, and by 5 o'clock he was well enough to be taken ten or twelve miles in a spring wagon, and arrived quite well, after an upset going down a hill. There were no symptoms of intoxication in this case. The spider which inflicted the wound in this case was killed and examined by the patient,

and proved to be a small black spider. Each of these two patients was a healthy man in the prime of life; exact age not known.

Case III.—I was called about 10 A.M., Oct. 6 1867, to see W., aged eighteen, who had been bitten by a spider of the same sort on the back of the left hand the night before, about seven o'clock. There was no pain, but only itching and redness at the part bitten at first; but violent pain soon commenced there and extended in a short time up the arm and forearm to the shoulder, and thence to the præcordial region. Plantain and some other domestic remedies were applied to the part without relief. When I saw him, the symptoms were grave enough to excite the apprehension of his parents, and to produce very great suffering in the patient, but, though like the two former cases, were by no means so severe. Milk-punch, in which form alone the patient would take whisky, was given freely, and ten grains of bromide of potassium and ten of bromide of ammonium, with three of iodide of potassium and a drachm of aromatic spirits of ammonia, were given in water every hour for four hours, when the patient was quite relieved.

Case IV.—A quadroon mulatto woman called on me about twelve o'clock, the night of September 23, 1874, to visit her daughter, a healthy woman, about twenty-two years old, who she said was suffering very greatly from pain in the right arm and shoulder, caused by the bite of a spider, small and black, which she killed when inflicting the bite about 7 P.M. Being in a copious perspiration following a fever from cold, I declined to visit the patient, but prescribed for her as in the last case. One dose of the medicine and punch was given, but, the patient growing worse, the mother would give no more. She called me up soon after day, begging me to go immediately to see her daughter, whom she thought to be dying. I found her apparently moribund; her skin as cold as marble; violent pain extending from the bite on the right wrist up the forearm and arm to the shoulder, and thence up the neck to the back of the head on the right side; more violent pain in the præcordia, extending thence to the shoulder and axilla on the left, and down the arm and forearm to the ends of the fingers, and this extremity partially paralysed; added to this, apnoea was extreme; the respiration only occasional—gasping; the pulse could not be felt in the left radial, and I was not sure that I felt it in the right. Having seen accounts of Halford's practice of injecting aqua ammoniæ into the veins for the bites of Australian serpents, I determined on its use (though I could not remember of what strength Halford used the ammonia); and as the water in the house was charged with salt, alum, and other impurities, I injected the strong aqua ammoniæ undiluted. Charging my hypodermic syringe with thirteen minims of aqua ammoniæ, I introduced the point carefully into a large superficial vein in the arm, which ran up the middle of the belly of the biceps, about the middle of the arm, holding the syringe almost parallel to the vein, and injected about two minims; and, waiting about an interval of a minute, two minims more, until I had injected ten minims. I was then about to withdraw the syringe, when the patient gave a spasmodic jerk of the forearm, pressing my right arm forward, and so pressing the point of the syringe through the vein into the cellular tissue, and sending home the piston, injecting the remaining three minims into the cellular tissue. I withdrew the syringe and placed my finger on the

pulse, where I held it about five to ten minutes. Feeling that the pulse constantly grew stronger and the skin warmer, I washed the syringe and replaced it in the case; when, looking at the patient, I was astonished at the calm and painless expression of her countenance, lately expressive of extreme anxiety and pain. On examining her pulse, it was full, regular, and beating only 77. The skin was warm and perspirable, and the respiration natural. She seemed to have been snatched *articulo mortis* and restored to health. To my question, 'How do you feel?' she replied, 'The most I have to complain of is the smarting where you stuck me in the arm.' On examining it, I found a blister there as large as my thumb-nail. A slough took place in a few days, which almost healed up kindly until she irritated the small remaining healthy ulcer while carrying a child on the arm to a picnic. Though a slough was the consequence of the injection in this case, yet it conclusively proves that dilute aqua ammoniæ may be safely injected into the veins; that it is only necessary to take care that none be injected into the cellular tissue, since no inconvenience followed the mingling of the strong ammonia with the blood in the vein, but only from its injection into the cellular tissue. To guard against such accidents, it is only necessary to open the vein to be injected with a lancet, and use a bulb-pointed syringe.

Case V. On September 28, 1875, I was called at seven in the evening to see Miss D., a healthy young girl, thirteen years old. At about half-past five o'clock she had thrust her right hand through a spider-web into a rose-bush to pluck a rose. She felt a stinging sensation on the wrist, accompanied by itching and redness at the spot. For several minutes there was but little pain, but in half an hour a painful sensation began to be felt at the spot, which quickly extended up the arm to the shoulder, and, in the course of an hour, along the neck to the back of the head. Several domestic remedies were applied to the spot supposed to have been bitten by a spider, but none affording any relief, and pain in the præcordial region with apnoea coming on, I was sent for. When I arrived, she was screaming fearfully with pain, and frequently exclaiming that she should lose her breath and die. The pulse had become thready and the surface cold. I had the bitten part rubbed with volatile liniment, and gave her at once the bromide of potassium and ammonium, and iodide of potassium with aromatic spirits of ammonia, and an ounce and a half of whisky, with water. Soon after swallowing the whisky and water, she said she felt a glowing sensation in the stomach, and not long afterwards a general glow. The skin became warmer, and the pulse grew stronger, with considerable abatement of the pain. At 8 P.M., a second dose was given; reaction continued to be developed, the pulse and respiration to improve, and the pains to abate. Just before 9 P.M., she fell asleep, and when I visited her in the morning, she had gone to school quite well.

The question arises, to what was the prompt recovery due in this case? Was it to the local application? Perhaps so; but more probably to the ammonia compounds finding from some cause an unusually ready admission through the portal into the general systemic circulation, not being eliminated in the bile by the liver, to be re-absorbed and required to go this round several times perhaps before gaining admission into the systemic circulation. That this is not unfrequently the case in regard to

our remedies, is rendered probable by what I have often observed in the treatment of pneumonia with the carbonate of ammonia, and which, I doubt not, others have also observed, viz., that after having been administered for twenty-four to thirty-six hours without apparent effect, it will suddenly produce its best effects on the pulse and respiration. To what other cause can this be attributable than that I have mentioned? But if aqua ammoniacæ can be safely injected into the veins, and produces the same effect we seek to procure by the administration of carbonate of ammonia in pneumonia, in increasing the force and diminishing the frequency of the heart's action, why should we not resort to the injection of the former in the treatment of pneumonia, and in all cases in which the same effects are desired?

BEARD ON ELECTROLYSIS OF BENIGN AND MALIGNANT TUMOURS.—In this paper (*New York Medical Record*) Dr. Beard relates cases to illustrate the uses of electrolysis.

Case I.—An enlarged cervical gland was treated by external applications of electricity. It suppurated and was opened. The cavity was then repeatedly electrolysed by a mild current from the negative pole, and gradually healed.

Case II. was one of ganglion of the wrist, of the size of a walnut. Both electrodes were inserted, and the negative was worked in all directions over the inner surface of the sac. Inflammatory action followed sufficient to obliterate the growth.

Cases III. and IV. were nævi of the face which involved the skin. They were destroyed, one by the action of the negative, the other by means of the positive pole. Cicatrices were necessarily left.

Case V. was one of hæmorrhage from the gums behind the upper incisor teeth. The gums were apparently healthy, but the patient suffered from and died of hepatic disease. On one occasion electrolysis arrested the bleeding for a week. The operation was repeated, but the effect is not reported.

Three examples of malignant tumour are given.

A scirrhous of the mamma was excised by Dr. Smith. Dr. Beard thereupon electrolysed the whole raw surface. Erysipelas followed, but the wound healed, and the patient left the hospital.

A small epithelioma of the face was removed by electrolysis of its base. The operation lasted half-an-hour.

An epithelioma of the cheek was treated by a somewhat complicated process. An incision was made in the skin, and the bleeding was arrested by placing a galvano-caustic wire in the incision. The tumour was then removed by electrolysis. It recurred. The operation was repeated, but the growth again returned.

Dr. Beard states in favour of electrolysis in malignant tumours; that the healing is satisfactory, that pyæmia does not follow, that the irritative fever is not dangerous, and that the cure is apparently more permanent than after simple excision.

[These cases show what electrolysis is capable of doing; they are unfortunate as selected examples of its usefulness. It was probably the best treatment in the case of hæmorrhage, and it is doubtless one mode of curing a ganglion which has resisted rupture and puncture. But in the enlarged gland it plainly did little if any good, and the other cases might with advantage have been trusted to ligature, the galvanic cautery, or the knife. There is no proof of the claims advanced by Dr. Beard on

behalf of electrolysis in malignant tumours. Experience points to its uselessness except for the relief of pain.—*Rep.*]

JOHN DUNCAN, M.D.

DUPLAY AND OTHERS ON THE TREATMENT OF DIFFUSE PHLEGMONOUS PERIOSTITIS.—A discussion on the treatment of diffuse phlegmonous periostitis lately took place at the Société de Chirurgie de Paris (*Gazette des Hôpitaux*, October 23, 1875). It related to a paper by M. Duplay, read at the above society on October 13, and of which a tolerably complete abstract will be found in *La France Médicale*, Oct. 22. The patient was a lad, aged sixteen, suffering from abscess in one of the phalangeal joints of the middle finger, and who was afterwards attacked with diffuse periostitis, rapidly passing on to abscess, and exposing nearly the whole shaft of the tibia. About a month after his admission into hospital, as his general condition was becoming grave (rapid pulse, high temperature, rigors, diarrhoea, delirium, etc.), M. Duplay found himself obliged to interfere by surgical operation. Relying on three published cases, one by M. Letenneur, of Nantes, one by the present reporter (both referred to by M. Ollier in his *Treatise on the Regeneration of Bones*), and a third by Dr. McDougall (*Edinburgh Medical Journal*, 1875),* M. Duplay determined to resect the shaft of the tibia subperiosteally, instead of amputating, especially as a separation could be detected between the lower epiphysis and the shaft. A free incision was made, the periosteum where it was adherent was easily detached, a chain saw was passed round the bone at the upper limit of the disease (as was believed), and the bone sawn through opposite the tubercle of the tibia. The diseased shaft was then easily extracted. Esmarch's bandage was employed. Very little blood was lost. The patient's general condition improved immediately, but the portion of the shaft which had been left kept up suppuration, and at the end of three weeks it became necessary to remove it also; the two together measured $28\frac{1}{2}$ centimetres, or nearly nine inches. The patient recovered perfectly, and with a thoroughly useful leg. In four months he left the hospital walking with a stick. The tibia had been reproduced, and the wound had healed, with the exception of a little sinus, which led to a sequestrum in the upper part of the bone. The tibia was, however, shortened by about an inch, and the fibula curved to accommodate itself to this shortening. No mention is made of any affection of the knee or ankle joints.

In the remarks on this very interesting and successful case which M. Duplay appends to the history, he dwells chiefly on the advantages of resection in such cases as contrasted with amputation; and in this respect no one seems to have contested his opinion. In fact, it is almost too plain to allow of discussion, that if a youth can be restored to health, with a limb only slightly shortened, and in other respects as useful as ever, it would be a grievous mistake to amputate. Nevertheless, it might perhaps have been as well to point out that in these cases resection of the bone is not always successful in avoiding the necessity for subsequent amputation. But the speakers who followed M. Duplay seemed rather to turn their attention to the question of the pathology of the disease, and to that of the necessity

* A fourth case is related by Mr. Spence in his recently published Address on Surgery at the meeting of the British Medical Association; but it was not then completed.

of resection as opposed to the expectant treatment, by incision and drainage, supporting the general health and strength with appropriate food and medicines—and afterwards removing any sequestra that may form. With respect to the pathology it seemed to be the general opinion that the bone does not perish, at least in its whole extent, unless the medullary tissue is also involved in the inflammation—*i.e.*, unless along with the diffuse periostitis there is also osteomyelitis. The opinion is at any rate a probable one, though the present reporter cannot see any proof of it sufficient to justify the axiomatic style in which it seems to have been announced by some of the speakers,* but it is really a point of minor importance. All that is needed for the surgeon's guidance in the practical treatment of the disease is to ascertain that the bone is thoroughly denuded of periosteum in the greater part of its extent, and that the patient's condition is so grave as to necessitate some surgical interference. The choice then lies between amputation and resection. If the surgeon temporise, it is true that the patient may yet survive, but the great probability is that he will die of pyæmia; and even if he do survive, a long, painful, and dangerous period is before him of successive operations for the removal of sequestra, a period often reckoned by years, and sometimes terminating after all in the loss of the limb. As to the precise pathological condition of the bone, it can hardly be ascertained except by examination after removal. No symptoms exist, as far as is known at present, by which the inflammation of the medullary tissue, if present in such a case, can be diagnosed. The more important matter surgically is to distinguish the cases in which immediate resection is indicated from those where it is better to wait. Everyone must admit with MM. Marjolin, Trélat, Guyon, and other speakers in this debate, that cases of periosteal abscess occur, threatening enough at first, but in which the general condition of the patient is not so profoundly affected as in M. Duplay's case, and in which the case may and ought to be treated in the expectant manner above indicated.

At the same time, the present reporter may be permitted to say that, in speaking of the case under his care, published originally in the *Lancet* for 1866, vol. i. p. 340, and afterwards in his treatise on the *Surgical Treatment of Children's Diseases*, M. Verneuil is completely in error in stating that the periosteum was adherent over two-thirds of the tibia. So far was this from being the case that it is expressly stated in the French translation of that work, 'La tuméfaction et la fluctuation perçues au niveau du genou et du cou-de-pied ne me permettaient pas de douter que la dénudation du tissu osseux ne s'étendit jusqu'aux limites de la diaphyse,' and this view was completely verified at the operation, when the tibia was found to be so completely separated from the periosteum that no instrument was required to detach it. He can, therefore, express his entire agreement with M. Verneuil in the opinion that it is unnecessary to resect the whole of a bone when only a third of its shaft is denuded; while, at the same time, he looks back with entire satisfaction to the treatment pursued in that case. The fact, also, is incontestable, as stated by M. Marjolin and M. Duplay, that the necessity for so grave a step as the resection of the whole shaft of a long bone is one which rarely oc-

curs. And, further, the success of resections limited to a portion of the shaft is far less probable than that of those in which the whole diaphysis has become separated from the periosteum, and can with a little gentle traction be detached from its articular extremities. It never was the present reporter's intention to recommend the resection of the bone, except in cases where, in the judgment of the surgeon, the death of the bone is either accomplished or inevitable, and in which nothing but a continuance and propagation of inflammation can result from leaving it. And he refers with confidence to his writings on the subject as expressing this meaning with sufficient clearness. M. Duplay's interesting case shows incontestably the success which may attend the attempt to save the patient's life without amputation in such instances. One rather singular omission in the debate, as reported (though the report is by no means so full as might be desired), is that of all reference to the abscess in the joints, which is liable to occur when the whole bone is affected. Abscess in the knee or ankle, or both, is very liable to happen; yet the limb may be saved—as is proved by the case often referred to in this debate; for, in that case, an incision was required into the knee-joint, and permanent ankylosis followed.

T. HOLMES.

WOODS ON A FOREIGN BODY IN THE BLADDER. — Dr. J. T. Woods, of Toledo, Ohio, relates the following case in the *Detroit Review of Medicine* for December 1875.

On the afternoon of July 30, John Leutsch, a Pole, aged 23, obtained possession of a string of beads belonging to his wife, long enough to go three times round her neck, and introduced them into his penis. In the effort he easily succeeded, and, after having satisfied his curiosity, was somewhat unsettled by finding that he could not remove them. Experiencing discomfort from frequent calls to urinate and the half a dozen inches of the string of red beads dangling from the end of his penis, he on the 31st consulted Dr. Hohley, who in his efforts at removal broke the string within the penis.

The following morning, Dr. Woods was invited by Dr. Hohley and Dr. Brown to visit the case in consultation. Introducing a pair of Gross's trachea-forceps into the urethra, Dr. Woods succeeded in removing twelve of the beads by slipping them off the string. The urethra being now clear, the introduction of a sound detected foreign solid material in the bladder.

It was at once determined to remove them by urethrotomy. The patient was accordingly placed in the position for lithotomy, and under the influence of chloroform. A staff being introduced, the membranous urethra was incised, and, introducing a pair of long-bladed polypus forceps, Dr. Woods seized the foreign body and drew it towards the orifice. Finding this too small, he incised the posterior wall of the urethra with a probe-pointed bistoury, when he succeeded in removing the mass of beads. Again introducing the sound, he found a single bead still remaining, which he removed.

The patient recovered readily from the influence of the chloroform, and, a pad and bandage being applied, with a catheter in the urethra, was placed in bed. No untoward symptoms followed; the leakage of urine by the artificial opening ceased in a couple of days, and in two weeks he was ready to go to work.

* In the tibia resected by the present writer, the medullary tissue at the point sawn through showed no trace of osteomyelitis; but the rest of the medullary cavity was not opened, in order not to spoil the specimen.

PILCHER ON TRACHEOTOMY AS A PRELIMINARY TO EXSECTION OF THE SUPERIOR MAXILLA.—Dr. L. S. Pilcher, in some remarks on tracheotomy made before the King's County Medical Society at Brooklyn (*New York Medical Record*, November 20) remarks that in operations involving the cavities of the mouth and nose, attended with profuse hæmorrhage, tracheotomy presents itself as a measure preliminary to the more important surgical procedure, whereby the special terrors and difficulties of such operations are removed. He relates a case of tumour of the superior maxilla, in which he operated.

The patient was a lady, over sixty years of age. Less than six months had elapsed since any trouble about the face had been noticed. The external deformity was but slight. At the earnest request of the patient, the operation was undertaken. Tracheotomy was performed as its first step, and during the remainder of the operation, ether was administered through the tracheal cannula. As the operation progressed, the disease was found to be far more extensive than had been expected. The entire superior maxilla, with the palate, the lateral mass of the ethmoid, and the body of the sphenoid were infiltrated with, or largely replaced by, encephaloid material. It was impossible to remove all without opening the cavity of the cranium, short of which only Dr. Pilcher desisted. Troublesome hæmorrhage was experienced only from the posterior palatine artery. This was quickly controlled by the galvanocautery. The patient rallied from the operation, and lived for more than a month, finally succumbing to cancerous disease of the liver.

This method of procedure was adopted by Dr. Jas. L. Little, of New York City, last winter, in operating for removal of a large fibroid tumour, occupying the posterior nasal and the upper pharyngeal region, with brilliant success.

[The author appears to be unaware (except perhaps through hearsay) of the ingenious device of Dr. Trendelenburg, of Berlin, for performing tracheotomy and plugging the upper end of the air-tube in cases of operation on the mouth.—*Rep.*]

BAUM AND ROSENBAACH ON SUCCESSFUL SUB-HYOIDEAN PHARYNGOTOMY FOR ROUND-CELLED SARCOMA OF THE GULLET.—Dr. J. Rosenbach, assistant at the Polyclinic in Göttingen, communicates a remarkable case, of which an abstract is given here, to the *Berliner Klinische Wochenschrift* of September 20 and 27, 1875 (nos. 38 and 39). He remarks that subhyoidæan pharyngotomy was first introduced by B. von Langenbeck. It is true that Vidal de Cassis and Malgaigne had proposed the operation before. Though both of them claimed it as their own, neither of them did it in the living subject; indeed, Malgaigne called it a kind of laryngotomy, whilst in fact the pharynx is opened above the larynx. Luschka and Richet both rectify this mistake, and give the proper name of subhyoidæan pharyngotomy to Langenbeck's operation. The operation was first done in hospital at Tahiti, by a French naval surgeon; by this means a fibrous new growth of the epiglottis and pharynx was removed from a tuberculous American. In nos. 2 and 3 of the *Berliner Klinische Wochenschrift* for 1870, B. von Langenbeck details five cases of this operation, two of which were done by himself. His first case (closely following Prat's, which was really first) required a very large pharyngeal wound. This he justifies by experience of suicidal self-inflicted

wounds, which often do well. He gives most precise and accurate details as to the operation and its surgical anatomy. But since Langenbeck's publication, it has very seldom been performed. One case for a foreign body is reported by Dr. Lefferts (*Wiener Wochenschrift*, no. 7, 1875). It may be a question whether the operation is done so often as it deserves to be. Dr. Rosenbach believes that the case in which Professor Baum lately performed this operation deserves to be recorded, not only for its favourable termination, but for other reasons.

H. Mucker, aged forty-five years, a native of the grand duchy of Oldenburg, had healthy parents; was married, and had six healthy children. He was a large, tall, powerfully built man, but had always been rather thin. His mother is alive, aged seventy-six, in good health. His father is said to have died at sixty, of 'gastric catarrh.' The patient had been a labouring forester, but through good conduct became a sort of foreman. He attributed his complaint to catching cold in his work. He mentioned particularly a dry feeling in the right side of his throat. A sweating-cure and camomile tea relieved the hoarseness and the pains in his neck, but the feeling of a foreign body in the throat remained. He could swallow and breathe well, but this feeling of something not belonging to him being in his throat grew stronger and stronger. About Christmas dry food could not be swallowed. The voice began to be affected in January, speech being arduous. At the end of February he spat up a bit of reddish 'tumour,' about half the size of the tip of the thumb. This gave temporary relief. But in March he became worse and worse. He could only take liquid diet. For eight days he had only taken milk, and that with difficulty. He was greatly emaciated. His voice had almost gone, and sounded as if his mouth was quite full. For fourteen days past respiration had been difficult; indeed, for eight days he was forced to keep his bed, as the least movement increased his dyspnoea. He could only breathe tranquilly when perfectly still. His sleep was disturbed by dreams, in which he fancied himself at work, and the movements he made or imagined brought on feelings of suffocation. Sometimes sudden movement brought on vomiting, which gave temporary relief. Dr. Duweliuss, of Vechta, was consulted, and sent the patient to hospital, after making the diagnosis of tumour of the pharynx. The journey brought on such suffocation and fierce delirium as to be nearly fatal.

On May 3, 1875, he was made an in-patient. His breathing was noisy and difficult; his voice whispering. Swallowing was very difficult; but after a long time he swallowed half a tumbler of water. On depressing the tongue, an irregular swelling of some size, covered with whitish mucus, projected over the back of the tongue. Exploration with the finger stopped his breathing so much, that Professor Baum did tracheotomy at once. The opening was made between the cricoid cartilage and the thyroid body, and a silver cannula inserted at once. After the tube was introduced there was a stoppage in his breathing, apparently from spasmodic expiration-movements. But regular breathing soon commenced. By means of an œsophageal tube, about thirty-five ounces of milk were given him. An attempt, with Muzeux's forceps, to drag away the tumour through the mouth failed; though a good piece of broken-down tumour was thus extracted. Next day a more careful exploration was possible;

and showed the upper surface of a reddish, irregular tumour, covered with a whitish crust in spots, stretching over the back of the tongue, and apparently about the size of a walnut. On depressing the tongue more, it was seen to be much bigger, and had several outgrowths and processes. Externally, the neck showed little abnormal; yet the interval between the larynx and the hyoid bone appeared considerably too great. The salient angle of the upper margin of the thyroid body, beyond the central notch in front, was $1\frac{7}{12}$ inch (four centimètres) from the lower edge of the hyoid-bone, when the head was very slightly bent back. This space also felt fuller than usual. There were no enlarged glands. The exploring finger proved the visible part of the tumour (when the mouth was open) to be only a part of a larger mass. It projected somewhat on the right side. The longest finger failed to reach the lower border of the mass, and at the same time failed to reach the aperture of the glottis. The tumour felt everywhere soft and uneven. No attachment could be felt, except at the back of the pharynx at the level of the os hyoides, where, in the horizontal direction, it seemed adherent for about $\frac{1}{2}$ of an inch. A second attempt with Muzeux's forceps failed to remove the tumour, though portions were torn off and pronounced by Professor Krause to belong to a round-celled sarcoma. The laryngoscope did not much assist in the exploration. Some further attempts were made with forceps; but on May 15 the operation of subhyoidan pharyngotomy was determined upon. Before operating, the common cannula in the trachea was changed for a modified Trendelenburg's tampon-cannula. [A figure, and long description of this, is given in the text. It may be briefly described as the addition to the ordinary silver cannula of a membranous outer envelope (*Condom*) made of intestine, and connected with an India-rubber tube, so as to admit of easy inflation and thus to plug the trachea efficiently. The modification consists in attaching a little balloon or bladder to the end of the tube, and then putting another piece of tubing on firmly at one side of the tube (so that the elastic tube has two branches, like a Y reversed), through which to inflate it. A spring clip, or pinch-cock, familiar to those employed in volumetric analysis, closes or opens the extra tube at pleasure. The tension of the air in the tracheal plug can thus be judged of at once, by looking at the little balloon or bladder which hangs round the patient's neck or lies on his bosom ('quasi puero in collo pendeant crepundia,' *Miles Gloriosus*, act v. sc. 1).—*Rep.*] Trial was made some days before the operation, whether the patient could bear this tampon-cannula, and whether narcosis could be easily induced. Both were found practicable, though violent coughing and expectoration of mucus necessitated the removal of the chloroform several times. This was, however, greatly due to the patient's excitable disposition. But he was soon well narcotised. His head was allowed to hang down, bringing the seat of operation on a level with the windpipe. The skin was divided to the extent of three and a half inches, immediately below the hyoid bone. Then, by means of two pairs of forceps, the anterior fibres of the thyro-hyoid membrane, and some subcutaneous tissues, were torn across. Two little cutaneous arteries spouted, and were at once compressed. Then the sterno-hyoid and thyro-hyoid muscles were divided, and more and more of the thyro-hyoid membrane

cut through. Then Professor Baum, deviating from Langenbeck slightly in order not to wound the epiglottis, pushed a silver catheter over the back of the tongue so that its point hitched in the fold between the epiglottis and the tongue, and so pressed the mucous membrane (with the yet undivided layer of the thyro-hyoid membrane) forwards, and cut both through upon the catheter. It was, however, not enough torn apart, but was pushed forward from the mouth with the index-finger, and again torn by forceps, and well dragged to opposite sides. The epiglottis was seized with a sharp hook, dragged forward, and held with fenestrated forceps. Now, the mucous membrane being put well on the stretch, the hyoid bone dragged up, and the epiglottis drawn down, the pharynx was well exposed. One lobe of the tumour already protruded. It was pinkish, soft, almost transparent, and much like a common nasal polypus. It was found to be lobulated, and was now easily seized, and removed with the fingers. Only on the right side, a somewhat tough portion about $\frac{7}{12}$ inch broad, and $1\frac{1}{4}$ to $1\frac{5}{8}$ of an inch in length remained, attached below somewhat firmly to the œsophagus. It was quite on the right side and lower part of the pharynx. The mucous membrane was almost all severed as far as the lateral thyro-hyoid ligaments. There was a good deal of hæmorrhage, and some blood was swallowed. But breathing was never interfered with, and no blood was ever expectorated. It was thought better to ligature the stump or pedicle, which was accordingly done with three ligatures, whose ends were brought out of the mouth and attached to the right ear. During the operation the epiglottis was slightly injured, partly from the forceps employed to seize it. The cutaneous wound was now brought together by deep sutures. The various portions of the tumour were not put together and weighed as they ought to have been. The bulk was about that of a common (fowl's) egg. The structure was that of a round celled sarcoma, the separate cells of which were from 0.009 to 0.021 millimètres in their largest diameter ($\frac{1}{266}$ to $\frac{1}{125}$ of an inch English). The smaller cells were quite round, the larger somewhat oval, yet so that the longer diameter was never twice that of the shorter. The nuclei were somewhat large, dark, and coarsely granular. In the recent state it was difficult to make out nucleoli; by chromic acid hardening one or two nucleolar particles were seen. The nuclei measured from 0.006 to 0.018 millimètres ($=\frac{1}{400}$ to $\frac{1}{140}$ English inch) in their greatest diameter—they were round in the round cells, oval in the oval ones. The nuclei were surrounded by a little clear non-granular protoplasmic material. In the firmer portions of the tumour many fibres of connective tissue traversed the cell-masses. In the softer parts the cells were heaped up with but little connecting-substance. In the softest spots, on the summit of the lobes, the naked eye could see numerous puncta, of the size of a grain of sand, in the sections. These were found by the microscope to consist of spaces containing a fine fibrillar network—doubtless due to coagulation of the original fluid contents of the tumour—of solitary round cells, either like lymph-corpuscles or like the cells of the rest of the tumour; and of some larger, paler, irregularly stellate cells, whose processes (*Ausläufer*) were continuous with one another and with the blood-vessels. They were much like the cells of mucous membrane. Lastly, there were in some of these spaces perfectly spherical plasma-corpuscles, some of which contained

granules. Many of the spaces contained vascular networks of larger and smaller vessels. The surface of the tumour was covered with squamous epithelium. The tumour must, therefore, be regarded as a polypoid round-celled sarcoma, whose basis consisted partly of firm connective tissue, and which had imbedded in it, in prominent parts, many portions of mucous membrane. The patient's recovery was interrupted by scarcely any bad symptom. Next day the tampon was obliged to be renewed, on account of its bursting. A little milk got into the trachea; but was coughed out through the tube. The wound was dressed with salicylic acid wadding. On May 22 the patient could swallow minced meat. On the 24th the tampon-cannula was removed. The sutures were removed next day. On May 30 both wounds were closed—viz. that of the tracheotomy and that of the pharyngotomy. On May 31 the patient was discharged cured—sixteen days after the operation.

MATERIA MEDICA AND THERAPEUTICS.

HOLMES ON GELSEMIUM SEMPERVIRENS.—The *Pharmaceutical Journal* for December 18, 1875, and January 1 and January 15, 1876, contains an useful *résumé* by Mr. E. H. Holmes of what is known regarding Gelsemium Sempervirens.

The plant was first used by the 'Eclectic' practitioners in America, its properties having been discovered by an accident which is narrated in the *Eclectic Dispensatory*. It was first brought into notice in the *American Journal of Pharmacy* in 1852, by Professor W. Proctor, but does not appear to have been sufficiently well known or esteemed in 1855 for introduction into the *United States Phar-*

macopœia published in that year. In the subsequent edition of that work, published in 1864, it appeared in the secondary list; and in 1873 it was considered of sufficient importance to be placed in the primary list of *materia medica*.

The plant has received several scientific names, and is at the present day placed in different natural orders by different authorities on systematic botany. In the *United States Pharmacopœia* the name Gelsemium Sempervirens is adopted, and Gray's *Manual of Botany* is the authority referred to.

The plant is commonly known in America as the yellow, wild, or Carolina jessamine, and also as woodbine. It grows wild on rich clay soil near small streams along the sea-coast from Virginia to the south of Florida. In Florida it flowers in March, but further north not until May or June. The pedicels underneath the flowers are covered with a number of small imbricated bracts.

The generic names Gelsemium and Gelseminum are often used indiscriminately, and thus confusion and doubt as to the plant spoken of are caused. The name Gelsemium is preferable for this reason, and also because it is the name adopted in the *United States Pharmacopœia*. It is, also, the one generally accepted by botanists in this country. The plant is not a true jessamine, and it is rather unfortunate that it should be often called the yellow jessamine in America, since there is a true jessamine with yellow flowers which is often found in cultivation.

The part of the plant official in the *United States Pharmacopœia* is the root. As met with in English commerce it occurs in two states—either in packets, prepared by the Shakers of New Lebanon, which contain the root in small pieces formed into a compact mass by hydraulic pressure, and in which state it is difficult to powder; or it is sold simply cut up into pieces varying from two to eight inches in length, and one-third to three-quarters of an inch in diameter. It is frequently mixed with about half its bulk of long wiry pale brown rootlets.

The so-called Gelsemium root consists chiefly of subterranean stem with a small proportion of true root; occasionally a slender piece of the aerial stem may be found intermixed, and is readily distinguished by its purplish colour and hollow centre, and by the silky or tow-like fibre, rendered visible when the epidermis is peeled off. The true root is hard and woody, slightly undulated in outline, very sparingly branched except in the slender pieces, externally of a pale brown colour, nearly smooth, and furnished with a thin scurfy cuticle which is slightly cracked longitudinally. When a transverse section is examined with a lens the bark of the root is seen to be very thin, and to consist of two layers—the inner one being usually almost as pale as the woody portion and of somewhat soft texture, the outer one is darker and more compact.

The medullium, or woody portion of the root, occupies nearly its whole diameter, is of a pale yellowish white colour, the yellow tint becoming much more distinct when the root is wetted. The medullary rays are white and very distinct, and the woody tissue between the rays is very porous; the pores being very small, but visible to the unaided eye, especially when the root is broken instead of cut. There is no pith or central cavity in the root.

The root has a bitter taste and pleasant flavour, and an odour somewhat between those of senega and green tea; this is more readily perceived in the tincture.

The subterranean stem is also furnished with rootlets, but is easily distinguished from the root by the presence of a small dark coloured central cavity representing the pith, and by the external surface being rougher and frequently variegated with dark longitudinal lines, which are the remains of the same purplish cuticle which presents so marked a feature in the aerial stem. The bark is thicker than that of the true root, and the inner layer is usually dark brown. If the subterranean stem is broken slowly and carefully a thin row of silky fibres projects fully a quarter of an inch from the broken edge. These fibres do not appear when the bark of the root is broken, and thus serve to distinguish the stem of this drug from the root. Experiments as to the relative value of the bark of the root and stem are wanting. The bark of the stem has the same bitter taste as that of the root; and if it be hereafter shown that it is equally active, the above character of the presence of scattered strong fibres, taken in conjunction with the flavour of the drug and its porous structure, will serve to distinguish it from all other roots or stems used in materia medica.

In this country Gelsemium has been used principally in the form of tincture. It has been found effectual in relieving neuralgic pain in the teeth and jaws, particularly when arising from decayed teeth. According to Dr. Mackey, it is especially beneficial when the pain occurs in parts of the face supplied by branches of the fifth nerve. Similar results have been obtained in Germany. In America it is largely used as a remedy in fevers, particularly those arising from malaria; in such cases it is often given in alternation with quinine. In minute doses it has been recommended in inflammatory and irritable conditions of infant life. It has also been used with success in dysmenorrhœa, in after pains, in spasmodic stricture of the urethra, in hysteria, and spasmodic croup. In traumatic tetanus it has been tried with the result of the death of the patient in six hours afterwards from paralysis of the muscles of respiration.

Gelsemium appears to be chiefly valued in America for its power in controlling nervous irritability in fevers, in which it is said to excel any other known agent. According to Dr. Bartholow, it corresponds more nearly in its action to conium than to any other agent. He also states that the action of Gelsemium is not practically antagonistic to that of strychnia or Calabar bean, and that the dilatation of the pupil caused by gelsemium is due to a paretic state of the circular fibres, and not to contraction of the radial fibres of the iris as is the case with atropia, and that it is not overcome by the application of extract of Calabar bean. From this it appears possible that gelsemium may prove of some service to the oculist in the form of a local application.

That this drug is a powerful poison there can be no doubt. The dose which has proved fatal, however, appears to vary with the age and constitution of the individual. Dr. J. N. Freeman, of New York (*Lancet*, 1873), mentions the following: Fifty minims of a tincture, consisting of four ounces of the root to a pint of diluted alcohol, proved fatal in two hours to a boy three years of age. Another boy three years old died in five hours, having taken in that time two doses of ten minims of the tincture. In a third case, in which two drachms of the tincture were given to a girl nine years of age, death ensued in two hours. In the last two cases the strength of the

tincture used is not recorded, and in the second case each dose was given with one and a half grains of sulphate of quinine. In the *American Journal of Pharmacy* (1870) a case is recorded in which a single dose of three drachms of the fluid extract proved fatal to a female adult in seven and a half hours. In another case alluded to in the *Practitioner* of October 1870, the administration of the drug proved fatal in two and a half hours.

According to Fredigke, the symptoms by which its effects manifest themselves in the animal economy seem to indicate that its energy is primarily exerted on the cerebro-spinal centres, and secondarily on the respiratory apparatus and the heart, the functions of the former ceasing before those of the latter. The symptoms are effectually counteracted by diffusive stimulants, such as strong cognac or whisky, given in doses of two ounces or less every hour, according to circumstances. All the symptoms will disappear after about two hours, leaving no unpleasant effects or derangement of the system.

The preparations which are used in medicine are the tincture, fluid extract, and gelsemin.

The 'fluid extract' is the only preparation official in the *United States Pharmacopœia*. It is made in the following manner:—

Take of—

Gelsemium root in very fine

powder 16 oz. (troy).

Alcohol (sp. gr. 0.835) . . . a sufficient quantity.

Moisten the powder with four fluid ounces of alcohol and pack it in a suitable percolator. The surface of the powder is then to be covered with a disc of paper, and the remaining portion of sixteen fluid ounces of menstruum is to be poured upon it. When the fluid begins to drop from the percolator close the lower orifice with a cork, and having closely covered the percolator to prevent evaporation set it aside in a moderately warm place for four days. The cork is then to be removed, more menstruum is to be gradually poured on, and the percolation continued until twenty-four fluid ounces have been obtained. Of these, the first fourteen fluid ounces are to be reserved, and the remainder having been carefully evaporated to two fluid ounces is to be mixed with the reserved portion and filtered through paper (if necessary). From this formula it will be seen that each ounce of the fluid extract represents an ounce of the root.

There is at present no recognised formula for the 'tincture.' The one given in the *American Dispensatory* consists of four ounces (troy) of the fresh root, cut into small pieces, to one pint of dilute alcohol. The pint used in the United States is officially only sixteen fluid ounces, hence this tincture is of the strength of one in four nearly. As the root probably loses nearly half its weight in drying, the quantity of fresh root ordered will be about equivalent to two ounces of the dried root, or one part in eight of proof spirit. Dr. J. N. Freeman, of New York, in a letter to the *Lancet*, speaks of a tincture of the strength of four ounces of the root to a pint of dilute alcohol. Drs. Sawyer and Mackey, of Birmingham, in a communication to the *British Medical Journal*, recommend a tincture made of the strength of two ounces of the dried root in coarse powder to two pints of rectified spirit. In London three of the leading houses in the drug trade prepare it in three different strengths—one using four ounces, another two and a half ounces, and another two ounces of the dried root to the pint

(twenty ounces) of proof spirit ; and other formulæ are used at University College and St. Bartholomew's Hospital.

From a comparison of the formulæ it appears that a tincture of the strength of two ounces (avoir.) of the dried root to sixteen ounces or twenty ounces of proof spirit is most generally used in this country.

A formula that shall reconcile the differences in the various formulæ used, that will not interfere with the one used by the majority of chemists, and that will enable those who use a stronger tincture to reduce it to a strength uniform with that generally used, is evidently an object to be attained. With this view the following formula is proposed :

Take of—

Gelsemium root (dried) reduced to coarse powder	2 ozs. (avoir.)
Proof spirit	20 fluid ozs.

Make the tincture by percolation, by the general process ordered in the *British Pharmacopœia* for preparing tinctures. An ordinary funnel answers very well as a percolator if a small plug of cotton wool be placed in the tube and covered with a layer of silver sand about one inch in depth, and if another layer of sand about half an inch in depth be placed on the top of the substance to be operated on.

Gelsemin is a preparation which is used chiefly by the Eclectics. It is prepared (according to Dr. Bartholow) in two ways, either by evaporating the tincture or by precipitating it with water. It must, therefore, evidently consist of the resin of the root with varying proportions of the active principle.

Of the powdered root, according to Dr. Sawyer, one to two grains is the dose. According to Dr. Tully, ten to fifteen grains have proved fatal to a child twelve years of age.

Of the dose of the fluid extract there is not any official statement in the *United States Pharmacopœia*. Judging, however, from the statement that the dose of the powder is one to two grains, and from the fact that the fluid extract represents an equal quantity of the root, and also from disagreeable symptoms having been produced by ten minims, the dose of the fluid extract may perhaps be fairly estimated at five minims. For children, the tincture is a much safer preparation.

Of the tincture the doses which are reported to have proved successful have been twenty drops of a tincture composed of two ounces of the root to sixteen ounces of proof spirit, given every three hours to adults ; and of the tincture made from two ounces of the root to twenty ounces of the spirit, fifteen minims administered in the same way. These doses have been given chiefly in neuralgic pain in the jaws and teeth, which have been cured within twenty-four hours.

KEYES ON THE EFFECTS OF MERCURY ON THE BLOOD OF SYPHILITIC PATIENTS.—Dr. E. L. Keyes read a paper on this subject before the New York County Medical Society, December 27, 1875 (*New York Medical Record*, January 8, 1876). His observations had special reference to the effect produced upon the number of red blood-corpuscles by the administration of mercury in the treatment of syphilis. With regard to the value of mercury in the treatment of syphilis, Dr. Keyes assumes the following position ; that syphilis is most surely controlled, and most often cured, by the unremitting use of small doses of mercury, just enough to restrain the symptoms without producing any conscious physiological effects, and continued for not less than

two years. The drug may be pushed if symptoms seem to require it ; is often continued for more than two years, and may be assisted by iodide of potassium. The opinion was expressed that when a syphilitic patient in fair health is treated in this manner from the period of his first eruption, he may be so cured that he will have but one general eruption, and no serious lesion subsequently ; that the health of such a patient will be as good after as before such treatment, and that the exceptions to the rule are not numerous. Reference was also made to the statement of Liègeois that small doses of corrosive sublimate increase the weight of healthy men or animals, and this conclusion was sustained by the clinical observations of Dr. Keyes. Dr. Keyes's experiments extended over six months, and were made upon persons in health, hospital patients, and patients in private practice. The blood was taken from twenty-seven individuals, of whom six were apparently sound, and twenty were syphilitic. Three hospital cases were used. The blood was counted 101 times, and from five to ten counts made each time. Dr. Keyes was assisted by Dr. A. L. Stimson, and observations on the following points were noted. 1. Average of red corpuscles in one cubic millimetre of blood of a healthy adult man—a high average is five millions. Anæmia rarely goes below three millions, and in five instances the count reached above six millions. 2. Effects of small doses of mercury on the blood early in syphilis. In all the cases counted, the number of red corpuscles increased under the influence of mercury, food, hygiene, and tonics. 3. Effect of long-continued use of small doses of mercury upon the blood in syphilis. There were three cases ; the drug was administered respectively eleven, six, and eighteen months ; the blood count was above the healthy average, and clinically they were all in excellent health. 4. Effect of mercury in excess on the blood in syphilis. In this, the only case in which salivation had been present (produced for special reasons), the count showed a loss of one million, attributed to the excessive use of mercury. 5. Effect of mercury combined with iodides on the blood in syphilis. In only two out of the nine cases under this head did the average count fall below the normal standard, and this among patients who had had syphilis for a long time. 6. Effect of mercury on the blood in syphilis in hospital cases. Three cases. One entered salivated, and the count increased after he began to eat. One showed a wretched count, being debilitated by disease and hospitalism, but improved under good hygiene and tonics, and it is believed the mercury helped him. 7. Effect of small doses of mercury on blood of individuals not syphilitic. The observations showed an increase in the count. The following conclusions were arrived at. 1. Mercury decreases the number of red corpuscles when given in excess, especially in hospital patients. 2. Syphilis diminishes the number of red corpuscles below the healthy standard. 3. Mercury in small doses, continued for a short or long time in syphilis, alone, or with iodide of potassium, increases the number of red corpuscles and maintains a high standard of the same. 4. Mercury in small doses acts as a tonic upon healthy animals, increasing their weight. In larger doses it is debilitating or fatal. 5. Mercury in small doses is tonic (for a time at least) for individuals in fair health not syphilitic. In such individuals it increases the number of the red corpuscles.

W. DOUGLAS HEMMING.

FRÄNTZEL ON THE TREATMENT OF ACUTE RHEUMATISM.—Dr. Fräntzel (*Charité Annalen*, Berlin, 1876), after having tried the various methods by propylamine, large doses of alkalies, and purgatives, has found his best results from following the practice of Davies in applying blisters in the neighbourhood of the affected joints. He orders strips of cantharides plaster, three fingers broad, to be applied round the limbs, two inches above the wrist, elbow, knee, and ankle joints, and below the shoulder and hip joints, so as to avoid blistering those portions of the body which press most directly on the bed. He afterwards gives a subcutaneous injection of morphia to procure sleep; in the morning he cuts the blisters and bathes them with warm water, and puts on warm-water compresses; in the evening these are removed, and the parts dressed with simple ointment. By that evening, or often by the morning, a remarkable improvement takes place in the condition of the joints, with diminution of swelling and pain; the fever abates, and often the temperature falls to below normal; 'only in those cases in which the joint-affection is not well pronounced, do the blisters remain without influence in the height of the temperature.' In cases in which four or more blisters have been applied, a certain degree of strangury or anuria is the result, and the urine contains blood-corpuscles, with hyaline and granular tube-casts, but this passes off in from one to four days, without leaving a trace. He protests against the idea that this method of treatment causes much suffering to the patient, for if half a grain of morphia be injected the pain resulting is very slight.

MACKENZIE ON THE TREATMENT OF WOUNDS.—Dr. A. C. Mackenzie, in the *American Journal of Medical Sciences (Medical and Surgical Reporter*, November 27), states that he treats wounds with much success with warm water and a balsamic compound. The warm water not only hastens the exit of disintegrated material, but conveys to the sufferer that soothing effect which heat alone communicates. The formula which he uses is the following.

B. Balsam fir,
True Venice turpentine,
Oil of sweet almond, aa ʒij
Add carbolic acid ʒss. previously dissolved in ʒij warm glycerine. M.

Apply with a flat camel's hair brush, and inject into the interstices of the wound with a glass syringe, having previously cleansed the wound with very warm water and a bulb-syringe.

Warm water is applied *ad libitum*, and the diseased or injured portion enveloped in flannel cloths, immersed in water as hot as can be borne comfortably.

GILL ON THE TREATMENT OF PRURITUS VULVÆ BY NITRATE OF ALUMINA.—In a note in the *St. Louis Medical and Surgical Journal* for December, Dr. H. Z. Gill says that in cases of pruritus vulvæ, whatever the cause may be, the nitrate of alumina has given more satisfaction than any other remedy or combination he has prescribed in a number of cases. The form in which he has used it is from four to six grains to the ounce of soft water, as a vaginal injection, or external wash. He ordinarily directs the patient to take a teaspoonful (beginning with rather less at first) of the powder, put it into a pint or a pint and a half of soft water, and use as a wash, or vaginal injection once, or if necessary, twice

a day. In hot weather it may be needed twice a day.

TREATMENT OF CHRONIC BRIGHT'S DISEASE.—In notes of practice and peculiarities of treatment at the Bellevue Hospital (*New York Medical Record*, January 1), the following plan of treatment is recommended in cases of chronic Bright's disease.

The patients should abstain as much as possible from meat. Milk should be substituted for meat, and should be associated with lime. Butter may be used; eggs if they agree, and fresh fish in the morning. Fried fats should be carefully excluded, but cream may be taken without stint. Vegetables and fruits are always good, but those should be selected which contain the least amount of woody fibre. Rice and potatoes, therefore, may be used, but asparagus, turnips, cabbage, and notably beans, which contain woody fibre in large quantities, should be assiduously avoided. Onions may be eaten with impunity, and are rather beneficial.

For the anæmia, iron should be administered from first to last, and by preference, the tincture of the chloride. This preparation is assimilated with difficulty; hence it should not be given alone, but combined with nux vomica, and to this spirits of nitre may be added to assist the determination towards the kidneys. For example, ten drops of the tincture of the chloride of iron, ten drops of tincture of nux vomica, and one drachm of sweet spirits of nitre may be given three times a day.

Cod-liver oil increases the red corpuscles of the blood, because it is digested by the liver, and the product enters into them as an ingredient. The irritability of the stomach may make it troublesome to take, but it should be relied upon as much as in the treatment of phthisis.

To combat the disease itself, one agent may be regarded as a specific against increase of connective tissue in the body, wherever the interstitial inflammation may occur, and that is the bichloride of mercury. It should be given in small doses (one-twentieth of a grain) and should be combined with a diuretic. For example, one-twentieth of a grain of the bichloride, one grain of digitalis, and one grain of quinine may be given three times a day, with the result of producing a specific action upon the kidneys, and will raise the specific gravity of the urine.

Attention to the condition of the skin will materially assist the embarrassed kidneys, and to do this we may have recourse to two things. If excessive oedema be present, the pressure produced shuts off the circulation to a great extent, and prevents removal of the fluid by diaphoresis. It is much better then to make punctures in the distended skin of the legs, and let the water drain away at once. No apprehension need be had with reference to this trifling operation, if the limb, when the punctures have been made, be wrapped with cloths wet in a solution of carbolic acid in water, to which has been added essence or oil of cinnamon. The latter is to correct the smell of the carbolic acid, and is equally antiseptic.

The second thing is, to rub the patient all over once a day with sweet oil. If extra diaphoresis be desirable, it can be best obtained by placing a blanket in an empty bucket, pouring hot water upon it, for in this way much less water is required, and then wringing it out and quickly applying it around the body and covering it with a dry blanket. The skin should be well oiled before the blanket is applied.

TREATMENT OF GANGRENE BY SALICYLIC ACID.—In some notes of practice at St. Francis's Hospital in the *New York Medical Journal* for January, it is stated that Dr. N. G. McMaster has used salicylic acid as an application to gangrenous surfaces, with marked benefit in keeping down the intolerable odour. One case, particularly, was satisfactorily treated in this way. Bromine had first been applied, then carbolic acid, then poultices of charcoal, but the odour was nevertheless sufficient to exclude the patients from the ward. The salicylic acid in powder was then either dusted on the surface or blown into cavities, as necessity indicated. After the thorough use of this agent, the offensive odour was completely controlled.

SCHUMACHER ON THE THERAPEUTICS OF MIGRAINE.—The *Berliner Klinische Wochenschrift* of January 7, 1876, contains a paper by Dr. Schumacher (II.), of Aix-la-Chapelle, on the pathology and treatment of migraine. He remarks that it is very difficult to find out the real nature of this disease. Romberg considered it a neurosis of the fifth nerve. Du-Bois Reymond and Brunner, from personal experience, regarded it as a tetanic or spasmodic condition of the cervical sympathetic, and of the smooth circular fibres of the muscular coat of the vessels. Möllendorf, on the contrary (himself a sufferer from the complaint), taught that the disease is due to a paralytic condition of the sympathetic, through which the vessels of the affected side are considerably dilated, and become overfull of blood, which gives rise to extremely painful sensations on the part of the sensory nerves of this region. The effect of remedies may give us some insight into the real pathology. On Du-Bois Reymond's hypothesis, antispasmodics will do most good. Amongst these, nitrite of amyl holds the first place. If we accept the opposite idea of a paralytic condition, our range of remedies is more restricted. Ergot of rye, however, ought to be a potent agent in such a condition. The following case shows that it is so. Mrs. St.—, aged forty-nine, is of slender build, and suffers from long-standing cyphosis, most marked on the left side. She has cardiac hypertrophy (chiefly of the right ventricle), and has not menstruated since the beginning of 1874. Her pulse is weak, but the heart's sounds are clear, and its impulse is somewhat excessive, even when the patient is at rest. Ever since she ceased menstruating she suffers from time to time, chiefly at night, from violent palpitation of the heart, with feelings like angina pectoris. These attacks last one to six hours, and have been most quickly relieved by subcutaneous injections of morphia. Since the beginning of December, 1874, the patient has complained of violent attacks of pain in the right side of the head; these attacks awoke her in the middle of the night, and were best relieved by getting out of bed. There seemed no reason for these attacks. Bicarbonate of soda, rhubarb, iron, in the day, and morphia and chloral-hydrate at night, only gave partial relief. Towards the end of January she lost the palpitations, but her pulse remained quickened, and she complained of dyspnoea in walking quickly. But the pains in the head became worse and worse, still chiefly on the right side; beginning between 2 and 3 A.M. as a boring pain at the back of the head, which radiated towards the front; the pressure over the eyes being worst, with throbbing of the arteries of the right side, and abnormally increased warmth of the suffering parts, which could

be felt by the hand. She was forced to get out of bed, and found relief, especially if she took coffee, from the cool air of the chamber. Towards morning the pain and other symptoms gradually abated, leaving her (when seen in the morning) very prostrate, and with some injection of the conjunctivæ; this redness vanished in the course of the day. Quinine in large doses gave only temporary relief. She could only bear morphia in small doses, and these only relieved her for a time. The induced (interrupted) current was of no use. The constant current from 6-8 cells for eight or ten minutes at a time, through the mastoid processes, or from the top of the sternum to the mastoid process, so far relieved her that she seldom had an attack the same day she was galvanised, and sometimes went from two to four days without one. But after about three weeks of electrifying the attacks were as bad as ever. She was awakened about 2.30 A.M. with boring pains in the back of the head on the right side, with radiations towards particular branches of the fifth nerve (rami masseterici), strong pulsation of arteries, a great feeling of heat, rushing noise in the right ear, reddening of the right half of the face. Towards morning the pains declined. The pulse was but little affected. Watery extract of ergot had been given in small doses without avail in February, but in April 1875 watery extract of ergot was given in pills, in doses of $4\frac{1}{2}$ to 9 grains. After she had taken (in fourteen days) about 5 grammes [about 77 grains], the attacks, though nightly, were weaker, so that she could remain in bed—with exacerbations every second or fourth day. Of the second 5 grammes, about $13\frac{1}{2}$ grains, were taken daily in pills, with still more relief. As this dose seemed pretty nearly a maximum, it was maintained. After taking 27 grammes [about 416 grains] of extract of ergot, she was quite cured of her migraine about the middle of May. In the month of July cardiac dilatation succeeded the previous hypertrophy, and she became dropsical, but there was no return of the migraine. It is noteworthy that the urine was constantly normal, and not affected by the administration of the extract of ergot.

PSYCHOLOGY.

MERSON ON THE INFLUENCE OF DIET IN EPILEPSY.—In this investigation (*West Riding Asylum Medical Reports*) twenty-four chronic epi-

leptic patients were selected and subjected to observation under two different kinds of diet, the one consisting largely of nitrogenous matter, and the other containing no animal food, but consisting of milk, arrowroot, potatoes, butter, oatmeal and bread. Dr. Merson distinguishes the former as nitrogenous and the latter as farinaceous. The exact dietary adopted in each case was as follows. Nitrogenous—*Breakfast*: eight ounces lean meat; beef or mutton, three ounces bread, one pint coffee. *Dinner*: twelve ounces lean meat, beef or mutton, seven ounces bread, varied occasionally with fresh vegetables. *Supper*: four ounces bread, four ounces cheese, and tea. Farinaceous—*Breakfast*: eight ounces bread, three-quarters of an ounce butter, one pint coffee. *Dinner*: on two days of the week, one and a half pints arrowroot milk, containing two ounces arrowroot and three ounces bread; on two days, oatmeal porridge, containing three ounces oatmeal to each man, with a pint of milk; on the remaining three days, twelve ounces potatoes, one and a half ounces butter, three ounces bread, and half pint milk. *Supper*: same as breakfast, except that tea was substituted for coffee.

In both cases the quantity is considerably less than what is usually considered as the average diet necessary for a healthy adult with moderate exercise. In this case, however, the amount of exercise was limited.

Previously to commencing the above dietary, each patient was accurately weighed, and his physical and mental condition noted. Twelve of the patients under observation were then put on nitrogenous diet, the other twelve on farinaceous; and this arrangement was continued for four weeks, during which time their physical and mental conditions were closely observed from day to day, and the number of epileptic seizures accurately noted. At the end of four weeks the weights were again taken and the diet changed, those previously on nitrogenous diet being transferred to farinaceous, and those on farinaceous to nitrogenous. After another period of four weeks, during which the condition of the patients was from time to time noted and compared with that which had been observed in the previous period, the weights were again ascertained, and the patients allowed to resume their ordinary dietary.

The results obtained during those two months of observation are not such as to justify the conclusion that either of the two diets used possessed any decided advantage over the other in the treatment of epilepsy. A reference to the tables, however, shows that as regards the number of fits in individual cases, there is a slight balance in favour of the farinaceous system.

With regard to the effect of these systems of diet upon the mental and physical conditions of the patients under treatment, it was observed that, in a considerable number of those who took nitrogenous food during the first month, soon after commencing that diet they became much more dull and stupid than they had previously been, would sit in a dreamy listless manner for a great part of the day, were very slow and languid in their movements, and took little notice of what was going on around them. This condition remained more or less throughout the whole period of nitrogenous food, though it varied in intensity at different times. No relation was traced between it and the recurrence of the fits. As soon as the diet was changed to the farinaceous, it was remarked that the condition of mental hebe-

tude began to pass off, and in some of the cases the change was very remarkable. The improvement in the mental condition was not always accompanied by any marked diminution in the number of fits.

The general physical condition does not appear to have been appreciably affected by one diet more than the other.

The temperature presented great variation in individual cases, some cases having a higher temperature under nitrogenous food than under farinaceous, some giving an opposite result. Taking the average of the whole twenty-four cases, the morning temperature was 0.2° higher under nitrogenous food than under farinaceous, being 98.7° in the former, and 98.5° in the latter. The average evening temperature presented a similar difference, being 98.7° under farinaceous food and 98.90° under nitrogenous. This result is not what was to be expected, considering the composition of the diet in each case. The dynamic value of the farinaceous was somewhat higher than that of the nitrogenous—a fact, which *ceteris paribus*, should give a higher temperature in a period of farinaceous diet. This may have some connection with the condition of stupor, previously noticed as having occurred during the nitrogenous period.

The urine was examined in twelve of the cases. The amount of urea was, of course, much higher under the nitrogenous regimen than under the farinaceous, being in the former case 65.4 grammes for the period of three days, and in the latter 43.12 grammes. The salts, with the exception of the chlorides, were all considerably increased under the nitrogenous fare. The phosphates estimated as phosphoric acid (P_2O_5), gave an average of 6.72 grammes under farinaceous food, and 7.43 grammes under nitrogenous. Similarly the sulphates, estimated as sulphuric acid (SO_3), gave 4.74 grammes under farinaceous diet and 5.72 under nitrogenous. In accordance with the increased amount of urea and salts, the specific gravity was much higher in the urine collected during the period of nitrogenous food.

With regard to the influence of the two different kinds of diet on the actual number of fits, the table shows that out of twelve cases, there was in nine a decrease in the number of fits occurring during the four weeks of farinaceous food, as compared with the number during a similar period of nitrogenous diet. In some of these the decrease was very considerable. The average number of fits in each of these nine cases was 26.2 for the period of nitrogenous food, and 19.8 for that of farinaceous. Of the remaining three cases, one had the same number of fits in each period; another had one more under farinaceous regimen than under nitrogenous. In the third case, the number under farinaceous diet was more than doubled. This patient was, however, subject to periodic outbursts of fits; and the case cannot, therefore, be fairly regarded as telling against the farinaceous diet.

Dr. Merson thinks, after making due allowance for all circumstances likely to tell in the opposite direction, that there are fair grounds for the conclusion that a farinaceous diet is likely to be more useful in the treatment of epilepsy than a nitrogenous.

H. SUTHERLAND, M.D.

SHORT ATTACKS OF INSANITY.—Dr. J. A. Campbell relates (*Journal of Mental Science*, October, 1875) the particulars of three cases of short attacks of insanity. One was in a girl aged eighteen who

was admitted into an asylum in a state of hysterical mania, which passed off in less than a fortnight, the patient being discharged in a month. Another patient, a woman aged twenty-five, was admitted in a state of depression with great emotional symptoms without delusions. This passed off, and she was discharged in a fortnight owing to some informality, but she had quite recovered. A third was a gentleman, aged sixty-four, who was admitted in a great state of excitement with hallucinations of vision. He was discharged recovered in less than a month. Dr. Campbell, in connection with the question of discharging patients, asks these questions: How long should a patient be kept under observation in an asylum? What is the probability of the recurrence of the disease, and within what time? In what manner are the patient's home surroundings likely to affect him? The length of time for observation may, he thinks, be reduced to the shortest limits in the following forms: Puerperal insanity, the tendency being towards recovery; Insanity of drinking in the acute form, abstinence alone being necessary to recovery; Forms of insanity dependent on debility or starvation, where an improvement in the bodily and mental state has been coexistent; Cases of insanity dependent on functional derangement as hysterical insanity; Cases of recurrent mania, where the history shows a tendency to a short attack and a long remission. The probability of a recently recovered patient continuing well is greatly increased by his going to a well-ordered home. Many return because they have to contend with home difficulties and circumstances which would try the sanest person. Those who must be kept under observation are patients whose prominent feature has been melancholia, in whom impulsive actions have been noticeable, or in whom recurrence of maniacal attacks has been frequent and uncertain. The tendency at present is to discharge patients who might be better kept in an asylum rather than to retain those who ought to be outside.

G. FIELDING BLANDFORD, M.D.

LOCHNER ON TRAUMATIC SOFTENING OF THE SPINAL CORD WITHOUT EXTERNAL INJURIES.—No. 42 of the Munich *Aerztliches Intelligenzblatt* (October 19, 1875) contains the report of two cases of the above by Dr. Lochner of Schwalbach. The first case was a serving man, aged fifty-two, who was almost an imbecile. On May 23 last, when drunk, he was struck by a comrade, and fell backwards to the ground, with his back across a stone. After a quarter of an hour he could walk home, but was unable to pass urine, though there was much *ardor urinæ*. After some hours urine passed, but he could no longer retain it, and it dribbled from him. On account of this incontinence he was brought to the district hospital. The abdomen was much swollen. The bladder was high above the pubes, and in spite of the continued dribbling of urine, the catheter drew off 2,000 cubic centimetres (about three pints) of urine. The bowels had not acted for eight days. The right leg was much swollen up to the groin, and he could scarcely move it; it was very painful when it was moved for him. A dose of salts moved the bowels, but everything was passed in the bed unconsciously. From forty-five to sixty ounces of urine were daily withdrawn by catheter, and much dribbled away. He had enlarged prostate. The urine was pale yellow, slightly acid, and free from albumen. On June 19 hiccup

set in, he became comatose, and died on June 23, just four weeks after the fall on the stone. At the *post mortem* examination of the spinal cord, the external surface of the membranes was little altered; but corresponding to the eighth and ninth thoracic vertebræ, the whole cord was softened to a pulsatous consistence, so as to be easily washed away with a running stream of water. The bladder was much distended, and its mucous membrane reddened and covered with pus. The pelves of the kidneys and ureters were somewhat dilated. The prostate was much enlarged; its middle lobe was three quarters of an inch in diameter. There was pus in the left pleura, and circumscribed pneumonia at the base of the left lung, with commencing gangrene. The interesting point was, of course, the softening of the cord, corresponding to the site of the injury. The parts below this had been paralysed, but not immediately; the paresis depending not upon immediate interruption to the transfer of impressions, etc., but to slower nutritive changes.

Yet, Dr. Lochner remarks, he would still have doubted if the spinal cord could be severely injured, whilst the investing canal was still intact, had not a similar case occurred, in the same year, in the practice of his colleague, Dr. Bruglocher. In this instance, a man, aged thirty-five, of powerful build, slipped down some stone steps in the frosty weather, in January, 1874, and was soon afterwards picked up dead. At the *post mortem* there were found several extravasations of blood on the pia mater of the brain, and in the front of the anterior lobe of the brain the grey substance had an extravasation of blood as large as a pea. The medulla oblongata was soft, its tissue of gruel-like consistence with punctiform extravasations of blood. The spinal cord at the level of the sixth cervical vertebra was torn across to the right and posteriorly, so that more than half of the cord was severed. Its tissue was of gruel-like consistence. Corresponding to this spot there was an effusion of blood within the membranes. The connective tissue in the posterior mediastinum, in front of the vertebræ, was much infiltrated with blood. On the occiput, there was a wound in the skin about one and a quarter inch in length. It appeared that the neck and head had been forcibly bent backwards in the fall. The cranial hæmorrhages may be explained in part by direct violence, in part by *contrecoup*. Dr. F. Betz, in his *Memorabilien*, 1873, Band xviii. p. 167, records a similar case in an athlete, aged twenty-six, and notes the rarity of such cases. This may, perhaps, justify the present record.

W. BATHURST WOODMAN.

CLOUSTON ON EPILEPSY WITH LESION OF THE CONVOLUTIONS.—Dr. Clouston (*Journal of Mental Science*, Oct. 1875) reports two cases of epilepsy with lesion of the convolutions. The first, a man, aged about thirty-eight, was found wandering about the town in a stupid state. When he became more sensible, nothing could be got out of him as to the place of his residence or his relations. He admitted that he had drunk hard and had had venereal disease. The expression of his face and his slow speech were like that of a man in a state of general paralysis, and as the lethargy and weakness passed off it was found that he had partial paralysis of one arm. Six months after admission he began to have severe epileptic fits, which were repeated periodically for years. He became incoherent, slightly weak-minded and intensely

irritable, especially after the fits. Nine years after admission he had cancer of the penis, which was amputated, but neither the operation nor the healing process had any effect on the epilepsy. In 1874 the glands of the groin began to swell and ulcerated, and up to his death, eight months later, he had only one fit. The inner plate of the skull-cap, when examined, was found eroded in a circular space three inches in circumference behind and above the right internal ear. Portions of the temporal, parietal, and occipital bones were so affected. The dura mater under this was rough on its outer surface and had many spicula of bone projecting, and was thickened in the centre to a quarter of an inch. It consisted here of three layers, one a firm white fibrous layer, a middle space of clear fluid, and then the thickened dura mater with an inner fibrous lining. Its inner surface all over the right hemisphere was mottled and slightly roughened by dusky iron-mould-looking spots, as if from old extravasations. The dura mater on the left side was somewhat thickened in one spot, but the bone under it was not rough. The upper part of the brain was normal; the under parts of both anterior lobes lying on the orbital plates were of a dirty brown colour, the convolutions being shrunk and softened, the softening not extending beyond the grey substance. The tips of both middle lobes were similarly diseased. In the lower part of the middle lobe several convolutions had undergone simple atrophy. The rest was exsanguine and œdematous but normal. The microscope showed that the dark soft spots on the convolutions were broken-down brain-tissue and masses of blood-colouring matter, the result of small apoplexies. The second patient was a male, aged thirty, admitted in 1868. He had been five years an epileptic, fits having followed a fall on the left side of the head. The fits had been becoming more severe, and he had been dangerous and violent. He had severe fits every fortnight or three weeks, both by night and day. He was at times quiet and comparatively rational, but usually stupid and very confused, and never able to employ himself. He had fits in the same way till his death, which took place in 1875, twelve years after the fits began. On examination, there was found in the squamous portion of the temporal bone an irregular excrescence of bone projecting upwards, and closely adherent to it the dura mater, arachnoid, pia mater and brain, all matted together by tough fibrous tissue. Two or three of the convolutions near it were atrophied, softened, and of a dirty-grey colour. The softening extended inwards as far as the ventricle, and the posterior end of the corpus striatum was slightly affected. The dura mater was adherent, and in one place much thickened. In the centre of this thickening was a small spiculum of bone in the arachnoid, about a quarter of an inch in diameter, and over this a small thin clot of blood in the dura mater. The brain-substance generally was pale and thick; there was interstitial atrophy round the vessels, causing a cribriform appearance. The medulla and pons were also in this state. The softened portions of the convolutions consisted of broken-down cells and fibres, while the white softening consisted of shrivelled white fibres, granular blood-vessels and increased nuclei of the neuroglia. Dr. Clouston remarks, that in these the epilepsy was regularly periodic as in ordinary hereditary epilepsy, where no lesion can be demonstrated. Therefore there must have been, in addition to the actual disease in limited parts of the brain, a tendency in

the whole organ to the irregular motor action that constitutes epilepsy. In both cases the lesions chiefly affected the periphery of the brain, confirming recent observations. The tendency for small apoplexies to occur everywhere inside the dura mater and in the grey matter of the convolutions in the first case and round the spiculum of bone in the second, is noteworthy, and not as yet sufficiently taken into account.

G. FIELDING BLANDFORD.

SOLTMANN ON THE FUNCTION OF THE CEREBRUM IN NEWLY BORN INFANTS.—Dr. Otto Soltmann contributes to the *Jahrbuch der Kinderheilkunde*, Band ix., a paper on the function of the brain in newly born infants. He adduces experimental evidence for the theory that during early infant life the spinal system performs more important functions than the cerebral system. For example, convulsions in children he refers entirely to the spinal nerves. In affections of the thorax and abdomen, in inflammations, fevers, and the exanthemata, convulsions are common in children; while in adults there only occur rigors, headache, or slight delirium. He goes on to show that the various movements are in reality reflex, or due to instinct. For example, closing the lids to protect the eye is not exhibited till the seventh or eighth week. The child is ignorant of danger; and it is not till the brain begins to act that the child recognises danger, and closes the eye accordingly. In favour of this view, he quotes from West.

He compares the relative amount of the grey and white cerebral matter as anatomically supporting his theory.

The effect of the constant current, when applied to Hitzig's centre in young animals, was not perceptible till they were twelve days old, and then only by contractions of the upper extremities. On the thirteenth day the lower extremities were sensibly affected by the current.

The theory is further supported by experiments on adult animals, which seemed to prove that they could be reduced to the condition of young ones by removal of Hitzig's centre.

The paper is accompanied by various diagrams.

ROBERT J. LEE, M.D.

OBSTETRICS AND GYNÆCOLOGY.

FÉRÉOL ON A CASE OF UTERINE DECIDUAL MEMBRANE EXPELLED WITHOUT HÆMORRHAGE, AND WITH THE SIGNS OF INTERNAL HÆMORRHAGE; PROBABLE EXTRA-UTERINE FETATION.—Dr. Féréol (in *Archives de Tocologie*, January 1876) narrates an instance of this nature. The patient was aged twenty-five, a sempstress, mother of two children. The last labour two years previously to the present attack, was followed by a severe attack of pelvi-peritonitis, which confined her to bed for three months. The catamenia had ceased two months. On July 20 she was in her usual state of health; whilst seated on a chair, she suddenly, and without any appreciable cause, experienced severe pain in the lower abdomen, which necessitated her going to bed, where she remained two days without any further symptoms. On the 22nd she continued her work—the pain being constant but slight. On the 23rd she was imprudent enough to go out;

on her return the pain suddenly became extremely intense, and she continued in a state of syncope, from which she scarcely rallied until her admission into the hospital on the morning of the 26th, when her condition was almost hopeless. She was bloodless, of a deathly pallor, in an almost incessant state of syncope, vomiting everything she took; the pulse small, thready, almost imperceptible, 120. The abdomen was distended, tympanic, extremely sensible to the touch, the pain not being referred to any one particular spot. There had been no external hæmorrhage whatever; a vaginal examination revealed a fulness in the right and posterior cul-de-sac; the uterus was immobile, the os patulous; no tumour was appreciable. The condition of the patient was so extreme that the question of transfusion was considered. In the meantime ice with a little brandy, depression of the head, and other means were resorted to. The vomiting ceased, and she began to improve.

On the 28th, two days after admission, on making a vaginal examination, the finger encountered a membrane lying free in the vagina; not a drop of blood, merely a little yellowish mucus, being passed with it. This membrane was triangular, thick, villous on one aspect, presenting on the other glandular apertures—a well marked decidua membrane. From this time the patient gradually improved; the pallor and weakness lasted some time; but ultimately convalescence was established.

DONNÉ ON ABLATION OF THE BODY OF THE UTERUS, IN CASES OF IRREDUCIBLE INVERSION, BY EXTERNAL HYSTEROTOMY.—M. Donné (*Archives de Gynécologie*, Jan. 7, 1876), in a recent communication to the Academy formulates the following conclusions.

1. External hysterotomy is an extreme surgical resource, but precious for cases of irreducible inversion, which threaten immediately the life of the patient.

2. This operation does not furnish a greater mortality than that of the greater number of grave operations.

3. In the actual state of science, it ought to be made preferably by the ligature, bearing in mind the perfection attained by this method.

4. For the first months of an inversion—even the first year, as far as possible, repeated tentative efforts at reduction, at lactation which generally suppresses the hæmorrhages, and all sorts of palliative methods, should be fairly tried.

The operation ought to be reserved for cases recognised as irreducible, and for the period remote from the commencement of the malady, when involution has completely taken place, and the neighbouring organs have undergone changes rendering the risk of peritonitis much less, this being very important.

THOMPSON ON LACERATION OF THE GRAVID UTERUS.—In the *Obstetrical Journal* for January and February, 1876, Mr. J. Ashburton Thompson contributes an interesting article on this subject, specially in reference to a recent trial, Regina v. Wood, where the question of manslaughter was raised on account of alleged malapraxis. The chief symptoms of this sad accident which he points out are—1. Violence of the throes before rupture; 2. A peculiar pain at the time of rupture; 3. Hæmorrhage; 4. Immediate cessation of the throes; 5.

Retrocession of the presentation; 6. The speedy occurrence of collapse; 7. Convulsions.

Reference to twenty-three unselected consecutive cases is given, and the occurrence or absence of individual symptoms in the several cases is commented on. He shows that variations from the classical descriptions of such cases are not only common, but are actually more common than the typical cases themselves. The aid to diagnosis to be gained from the character of the uterine contraction was in 73·4 per cent. none; from the occurrence of characteristic pain at the moment of rupture in 57·8 cases per cent., none; from the action of the uterus subsequent to rupture in 47·1 cases per cent. none; from the sudden occurrence of collapse in 66 cases per cent. none; from retrocession of the child (in cases where retrocession was not mechanically obstructed) in 75·8 cases per cent. none; from the symptoms of external hæmorrhage and of convulsions, none.

From a general view of these cases, it appears that in some an early diagnosis of the patient's condition was impossible, for the simple reason that they showed no extraordinary symptom whatever; while in many, although the condition of the patient attracted attention, there was no one symptom marked enough, or any combination of lesser symptoms, which would have justified the diagnosis of laceration had the presence of that injury been suggested.

A. W. EDIS, M.D.

CUMMING ON THE UTERINE SOUFFLE AND THE FETAL HEART.—In a paper read before the Obstetrical Society of Edinburgh (*Edinburgh Medical Journal*, September, October, and November, 1875), Dr. James Cumming gives a detailed account of the views generally accepted with regard to the results of auscultation in pregnancy, and adds some original observations with regard to the relation between the rate of the fetal heart and the sex and weight of the child. He adopts the view that the uterine souffle is produced by the vessels which ramify in the uterine walls, and that it has no relation to the position of the placenta, or the integrity of the circulation through it. Out of 111 observations on the rapidity of the fetal heart, Dr. Cumming found that correct predictions as to the sex of the child exceeded the incorrect by only thirteen. From observations on the weight of the children, he concludes that this uncertainty depends on the fact that the pulse-rate varies not only with the sex but with the weight, and that thus a large female child may have a slower pulse than a small male. The result at which he arrives is, that the ratio between the weight of the child and the fetal pulsations is about 19 beats per lb. for the male, and 20·2 beats per lb. for the female.

A. L. GALABIN, M.D.

BYFORD ON THE TREATMENT OF FIBROUS TUMOURS OF THE UTERUS BY ERGOT.—Dr. W. H. Byford has devoted his address in obstetrics and the diseases of women and children, delivered before the American Medical Association, to a discussion of the treatment of fibrous tumours of the uterus by ergot. He has collected a large number of cases related by various authors, in a notable proportion of which the complete disappearance of the tumour was recorded, and in most of the remainder an amelioration of the symptoms of hæmorrhage and leucorrhœa. The whole number of cases treated was 101. Of these 22 are reported cured, and only 21 entirely resisted the treatment. The ergot was given

in three different ways: 1. by the mouth; 2. by injection into the cervix uteri; and 3. by injection into the cellular tissue, generally of the abdomen. The last method is apt to cause local irritation, but this effect depends in some measure on the preparation used. Dr. Byford prefers a fresh aqueous solution of the solid extract prepared by Squibb. A quantity representing from 60 to 120 grains of powdered ergot is injected once daily, or once in two days. Advantage is also gained by the combined use of belladonna and of the bromides and iodides.

LUSK ON THE GENESIS OF AN EPIDEMIC OF PUERPERAL FEVER.—In the *American Journal of Obstetrics*, Professor Lusk gives an account of the genesis of an epidemic of puerperal fever, which took place in the Bellevue Hospital in the early months of 1874. He commences the history at the end of August 1873, at which time there was a fatal case of peritonitis after delivery by forceps, and rupture of the perinæum. Soon afterwards there occurred five other cases of febrile disturbance a few days after delivery, but ending in recovery. The patients were on this account transferred to another ward, and the sanitary condition remained satisfactory from that time till November 10, when the case occurred which seemed to be the starting point of the epidemic. A woman was delivered after a dilatation stage lasting forty-five hours, but an expulsive stage of only a few minutes. On the third day the temperature rose to 104.7°, pulse to 140, and on the seventh day she died. *Post mortem*, no peritonitis was found, and no lesion except slight endometritis. From this time febrile attacks began to appear, although not at first of a fatal character. During the remainder of November, 10 cases out of 24 had rigors on the third day, and one died. During the month of December, out of 44 deliveries there were 24 cases of febrile disturbance and three deaths. In the middle of the month the ward was changed, but without effecting any improvement. With the commencement of January new resident physicians came into office, but without bringing any favourable change; for out of the next nine patients delivered seven had febrile symptoms, and three died. The epidemic continued, and in March it was noted that the patients appeared affected before the completion of labour. Its duration was prolonged, and the uterus could not be got to contract after delivery. Diphtheritic ulcers in the genital passages began to be a common feature in the cases seriously affected. Micrococci were found beneath the deposit, and scattered through the tissues of the uterus. At first prompt cauterisation had a surprising influence for good, but later on the miasmatic condition seemed to find other channels of entry, and local cauterisation ceased to have any marked efficacy. Dr. Lusk considers that the contagion was mainly communicated by the nurses, who were deficient both in number and in quality. He himself, although spending some time in the hospital daily, had no single case of febrile disturbance among patients attended in private practice. The wards were at length closed on June 11, when there had been 31 deaths out of 166 deliveries since January 1. Dr. Lusk draws the following conclusions. 1. Puerperal diseases may be engendered by the miasmatic atmosphere of a ward alone. 2. There is an eminently contagious form of puerperal fever, not primarily derived from a miasm, but capable in time of generating a poisoned atmosphere.

A. L. GALABIN, M.D.

TARBELL ON REDUCTION OF CHRONIC INVERSION OF THE UTERUS BY PERSISTENT MECHANICAL PRESSURE.—In the *Boston Medical and Surgical Journal* for January 13, Dr. Tarbell, of Massachusetts, relates the case of a woman, aged thirty-seven, who was admitted into hospital on account of inversion of the uterus, which was first perceived on the third day after labour, ten months previously. Various unsuccessful attempts had been made to reduce it. Dr. Tarbell and Dr. Minot attempted reduction first by manipulation, and then by an India-rubber air-pessary, inflated, and left in the vagina for five days; but without success. An attempt at reduction, after making longitudinal incisions in the os and cervix, also failed.

Dr. Tarbell procured a flexible India-rubber cup, of about the size of a half lemon, and with a straight and inflexible stem eight inches long. The cup was applied to the inverted fundus, and the end of the stem, projecting some distance from the vagina, was attached by straps, one over the pubes and one over the sacrum, to a belt fastened around the waist. The crest of the ilium kept this belt from being dragged downward; and by buckling the two straps tighter or more loosely, the direction and amount of the force applied could be easily regulated. Both straps were buckled tightly, and the patient was kept upon her back in bed. On the second day she had a chill with subsequent fever (temperature 102°), and some tenderness of the abdomen. The instrument was removed, and in four or five days these symptoms subsided.

The cup with the stem was now reinserted, and the straps tightened so as to produce constant firm pressure upward against the whole fundus. On the third day the os seemed to have yielded so as to allow a small portion of the cervix to resume its normal position. On the seventh day the uterus was reinverted one-half, so that the fundus was at a level with the os. The cup was then cut off, leaving only its base, a flat surface three-fourths of an inch in diameter, to be applied to the fundus. On the eighth day this was found to have passed one and one-half inches up within the cervix, pushing the fundus before it; and on the ninth day of the continuous pressure the inversion was completely reduced, the sound passing three inches above the os.

During the treatment there was a profuse foetid and purulent discharge from the uterine surface, which, in the exhausted condition of the woman, might easily have proved the origin of septic poisoning, had it not been for the abundant vaginal douches of tepid water frequently given by a skilful nurse, in such a manner as not to disturb the apparatus.

Three and a half months after the treatment, the patient was rapidly recovering from the extreme anæmia, and called herself quite well. She had menstruated regularly each month, though the flow was but slight. The uterus was in normal position, was not painful or tender to touch, and the sound entered two and three-fourths inches.

In his comments on the case, the author quotes Dr. R. Barnes's opinion in favour of this method of treatment.

DAVIS ON THE TREATMENT OF PLACENTA PRÆVIA.—The Report of Luzerne County Medical Society (*Transactions of the Medical Society of the State of Pennsylvania*, vol. x., part 2) contains an account of a mode of treatment of placenta prævia,

adopted in these cases by Dr. R. Davis. The following is the procedure as described by the author.

'Having ascertained that the placenta was detached to a greater extent on one side than the other, I introduced my hand on that side between the placenta and uterus, carefully separating them where they were still united, until the border of the placenta was reached; then, seizing the border with three fingers, I drew it down forcibly to the other side of the uterus. I now found that the bag of waters protruded and the head presented. I ruptured the bag of waters, and immediately the head engaged in the os, and crowded the placenta to the side of the uterus. Here was a condition of things which I had observed before, in four cases of partial placenta prævia, in which the labour ended either naturally, or by the use of the forceps, and in which there was no further hæmorrhage after the placenta had thus become detached on one side.'

Dr. Davis remarks that the number of cases in which this treatment has been adopted is not sufficiently large to warrant any conclusions as to its superiority over other modes of treatment, but something may be said in its favour on general principles.

1. It leaves the connection between the uterus and placenta on one side of the uterus undisturbed, and that, presumably, on the side of the most extensive connection; a consideration of much importance, as regards danger to the child.

2. It dispenses with the necessity for the operation of turning, a confessedly dangerous operation for the child, and one not devoid of danger to the mother.

3. In case the operation of drawing the placenta down to one side, as described, is successful in arresting the hæmorrhage, then the case is converted into a natural labour, and may be either left to nature or terminated by the forceps; but, should the hæmorrhage be not arrested and the forceps impossible of application, there is still nothing to prevent a resort to version, the same as if the operation had not been performed.

The performance of this operation presupposes a dilated os; and therefore, as dangerous and sometimes fatal hæmorrhage is liable to occur before dilatation has taken place, it is not alleged that this operation meets all the difficulties which may be encountered in a case of placenta prævia.

PINCUS ON RUPTURE OF THE LIVER IN NEW-BORN INFANTS.—Dr. Pincus relates in the *Vierteljahrsschrift für gerichtlich. Medicin und öffentl. Sanitätswesen* for January 1876, three cases of this rare lesion.

Case 1.—A woman, who had already borne two children, was confined of a third child, which, she said, was stillborn. She stated that, not believing that her confinement was so near, she was seized with labour-pains while in a cellar, and that the child was born feet foremost and precipitated on the paved floor. Believing the infant dead, she put it in a vessel, covered it, and returned to her work. When examined two days afterwards, the child was found to be of full term, and to have breathed at the moment of birth or immediately afterwards. There were no external signs of violence, but in the abdominal cavity there was a large extravasation of blood derived from a rupture of the liver. The laceration extended through nearly the whole thickness of the middle of the right lobe; it commenced four-fifths of an inch from the margin, and ran back-

wards in a straight line for about two inches. The edges of the laceration were notched, the surface rough, and covered with partially coagulated blood. The whole liver was anæmic, as were also the other abdominal viscera and the vessels of the thorax. Nothing remarkable was found in the umbilicus or funis.

Dr. Pincus and his colleague Dr. Seydel were of opinion that the child had been born alive, and had breathed (though imperfectly), and that death was the result of rupture of the liver from some mechanical cause acting probably after birth. The lower border and other parts of the surface of the lungs were of a clear cinnabar-red colour; they floated in water, were crepitant, and on being compressed under water discharged bubbles of air. Commencing respiration was cut short by the rupture of the liver, which produced death by hæmorrhage. The rupture could only have been produced by mechanical violence, and this was not contradicted by the absence of external signs of injury. It could not, however, be admitted that the rupture was the result of a fall in the manner stated by the woman, the distance being but small, besides which, the force of the fall would have been broken by the umbilical cord. It was inferred, then, that most probably the violence had been applied to the infant's body when it was scarcely born. The woman was tried, and sentenced to three years' imprisonment for voluntary homicide. She afterwards confessed that she had caught the child by the abdomen; but Dr. Pincus doubts whether the rupture could have been produced in this way.

Case 2.—This was a case of an illegitimate child occurring in Dr. Thiele's practice. A widow, aged forty-three, became pregnant, and was seized with labour-pains. She stated that she fell senseless, and on recovering found the child lying cold and motionless between her legs. She ruptured the cord, which was twisted several times round the child's neck; and fearing that the infant might revive and cry, she filled its mouth. The body being discovered, a judicial examination was made with the following results.

The mouth was filled with earth and moss. At the bottom of the pharynx was a stone, which could only be removed by incision. There were signs of injury about the back. The umbilical cord was torn, and had not been tied. The abdominal cavity contained dark blood, and there were clots on the intestines and liver. The liver was anæmic, and the right lobe was torn, the edges of the rupture being notched and of a paler colour than the remainder of the parenchyma of the organ. Near the rupture there was a slight effusion of blood beneath the peritoneum. The kidneys were anæmic; the vena cava contained a little fluid blood. The lungs contained air, and floated in water. The heart was empty; there was a little dark blood in the great vessels. There was some sanguineous effusion beneath the cranium, and a little blackish blood in the meninges. The cranial bones were uninjured.

At the judicial examination, none of the medical experts held that the child had been born alive, and had died from the impediment to respiration or from rupture of the liver, or from both these causes together; and they attributed the rupture to traction on the umbilical cord. Others, however, declared this opinion contrary to all facts, inasmuch as rupture of the cord in sudden delivery occurred without lesion of the liver. Further, any force that might

be exerted by the cord would pass not only to the umbilical vein but to the arteries, and would thus be distributed in various directions. They, therefore, concluded that the rupture of the liver was the result of a blow or other violence applied externally. The woman was sentenced to three years' imprisonment.

Case 3.—A woman was confined, as she said, while insensible. She also said that for the purpose of arresting bleeding she filled the child's mouth and nostrils with straw; it having died, she buried it and returned home.

Examination showed that it was born at full term, and had breathed completely. The heart and coronary arteries were void of blood, while the large thoracic vessels contained some fluid blood. On moving the body dark blood escaped from the mouth and nose. On the upper lip, chest, and back were some livid spots. There was a copious effusion of fluid blood in the abdomen; the liver (which was not anæmic) presented in the right lobe a deep crack, with notched edges. The other organs and the vessels were deprived of blood. There was sero-sanguinous effusion in the pleuræ; the lungs presented the characters of complete respiration, and there were some petechial spots under the pleuræ. There was a little blood in the meninges and brain. There being no sufficient reason for discrediting the woman's assertion that she was senseless when delivered, judicial proceedings against her were not carried out.

A. HENRY, M.D.

BIXBY ON THE DRAINAGE OF THE PELVIS.—In the *Boston Medical and Surgical Journal* (November 18, 1875) Dr. Bixby, of St. Elizabeth's Hospital for Women in Boston, describes a new instrument for the ready and effective use of the double current in the treatment of suppurating cavities and in pelvic drainage.

The instrument, which he denominates the double trocar, consists of a cannula ten inches long and one-fourth of an inch or less in diameter, straight or curved according to its particular use. A horizontal septum divides its cavity into two equal chambers, the inferior extremity of each being fenestrated to the extent of an inch. Superiorly each chamber is connected by a branch, the afferent and the efferent, with rings and guard for retention. Into this double cannula there fits a flexible double trocar attached to a common handle, and answering for both the curved and the straight cannula. When the trocar is inserted and forced home, the two extremities come together in sufficiently close apposition to form a single point. A piece of India-rubber tubing two or three inches in length, attached to the afferent branch, forms a convenient coupling for the nozzle of the syringe, and the efferent is lengthened to the desired extent by the same means. The copious and uninterrupted current and the absolute immunity from the admission of air, obtained by the use of the fountain-syringe, render that instrument, or an apparatus constructed upon the same principle, absolutely indispensable to the use of the double cannula.

While the double trocar has all the advantages of the single instrument, it possesses the additional advantage of establishing at the same time a complete appliance for the double current. From the copiousness of the current obtained by means of this instrument, it has all the advantages of a large opening, without the dangers of hæmorrhage, and with less risk of self-inoculation.

This instrument is recommended in the following conditions.

With straight trocar and cannula in—1. Pelvic abscess; 2. Retro-uterine hæmatocele.

With straight cannula alone and blunt point, in—3. Pelvic abscess and hæmatocele, when a free opening is preferred and when there is a multiple sac.

With the curved instrument in—4. Pelvic drainage after ovariectomy and abdominal operations.

With straight cannula alone, in—5. The uterine cavity after the removal of intra-uterine and interstitial uterine fibroids; 6. The uterine cavity in acute puerperal endometritis, offensive *post partum* vaginal discharges, for the application of cold and of astringents in *post partum* hæmorrhage, and for the treatment of the female bladder.

1. *Pelvic Abscess.*—The patient, etherised and with a bandage passed around the waist, is placed upon the left side across a bed or upon a table; the limbs are sharply flexed, or, if preferred, in the lithotomy position. The uterus, if not anteverted, which is more often the case, should be so placed, if it be possible; if necessary, it should be held in that position with a sound. The diagnosis is then confirmed with an aspirator, the depth required to reach the fluid being carefully noted.

Since a complete or even a partial evacuation of an unilocular cyst would cause it to become flaccid, and would render further operative interference exceedingly difficult if not dangerous, the least possible amount of fluid drawn the better. The most prominent part of the tumour having been ascertained, and the seat of the pulsation of large vessels avoided, the trocar, with concealed point and armed with the guard and with both India-rubber tubes in place (the afferent closed with a stopper, the efferent tied in a single knot), is introduced into the vagina upon the finger of the left hand and placed firmly against the tumour. With the left hand in the vagina, controlling the extremity of the trocar, the puncture is made in downward direction with a firm but steady force. The peculiar impression imparted as the instrument passes into the cavity is quite unmistakable. The previous arrangement of the tubes prevents a sudden escape of the fluid. The trocar is now withdrawn sufficiently to conceal its point, the guard secured against the vulva, and the tapes for retention applied. The last step is best effected by passing them through the staple, around the limb, under the bandage around the waist, and finally tying or, what is better, buckling the extremities together in front. The patient being on the left side, the right tape is first applied, and will retain the instrument until she is turned upon the back, when the other is adjusted. If the operation be performed with the patient on her back, both tapes are put in position at once. The patient is now placed upon the back, near the edge of the bed, and the left tape adjusted. We may evacuate the abscess at once, but the better plan is to attach to the afferent branch the tube of a fountain syringe charged with a disinfecting solution, and suspended or held six feet above the bed, at the same time untying the knot in the efferent branch and placing its extremity in a vessel on the floor beside the bed. The trocar is now withdrawn without fear of displacement, the central opening of the cannula is closed with a stopper, the stop of the syringe is opened, and the contents of the abscess are forced out by the strong current.

We have now in position a convenient and ever ready appliance for the use of the double current, with little risk of displacement, of easy application by the most inexperienced attendant, and with slight annoyance to the patient. The frequency of the application should depend upon the nature of the discharge and its effect upon the system. Dr. Bixby usually commences the treatment with three daily applications and one at midnight. Under all circumstances the application should be copious. The efferent current should be frequently interrupted, the cavity thus filled, and contact with every part of it secured. He uses a five per cent. solution of carbolio acid (two drachms to sixteen ounces of glycerine, soap, and water) as by far the most efficacious.

2. *Retro-Uterine Hæmatocèle.*—Notwithstanding the recommendation by most authorities of a free opening in the treatment of this affection, Dr. Bixby attaches much importance to the method above suggested in connection with the treatment of pelvic abscess, for the reason that, as the aspirator indicated in all his cases, the contents of the cyst are composed, even in the late stages, not only of coagula but of a large amount of sero-sanguinolent fluid. After what seemed to be a complete evacuation after the free opening, the cavity continued to secrete for weeks a purulent, offensive discharge, as if from a pyogenic membrane.

3. *In Pelvic Abscess and Hæmatocèle,* after free opening, the use of the straight cannula with probe-point, in connection with the fountain-syringe, will be found to render invaluable service.

4. *Pelvic Drainage after Ovariectomy.*—When the operation has reached the stage prior to that of the closure of the wound, after applying a bandage around the body, the surgeon passes the left hand into the pelvis along the pedicle until it reaches a point in the reflexion of the peritoneum opposite Douglas's fossa, and with the right hand introduces the trocar into the vagina, armed with its guard, its afferent and efferent tubes adjusted, and its point concealed. With bimanual manipulation, the extremity of the instrument is placed against Douglas's cul-de-sac, as low as possible below the uterine connection, without impinging upon the rectum, and held firmly in position. An assistant pushes the trocar through the vaginal septum, its passage being guarded and controlled by the operator's left hand, still in the pelvis. This done, the point of the trocar is concealed by a slight withdrawal, the instrument tilted upward and forward, and the extremity of the cannula protected by a probe-point. The guard and tapes are adjusted as in pelvic abscess, and the trocar is entirely removed.

The cannula being in position as above described, as in pelvic abscess, the hose is attached to the afferent branch and the efferent tube is placed in a vessel beside the bed. The first few hours a sero-sanguinolent discharge usually flows of its own accord, but this being the usual stage for the formation of coagula, at least as soon as six hours after the operation a current of tepid water, slightly carbolised, should be allowed to make the circuit of the instrument, merely for the sake of insuring patency. If at the end of four or five days the fluid escape in the same condition as when it entered, and there be no untoward symptoms present, in all probability the necessity for drainage has ceased, and the cannula may be removed with impunity. Leaving the instrument in position a longer or shorter period, even after

this stage, its presence being, in Dr. Bixby's opinion, indifferent, must depend upon the judgment of the surgeon. If, on the other hand, early after the operation, or even a few days later, we discover local or general signs of putrid accumulation, the injection should be copious, frequent, and highly disinfectant, and the case treated precisely as one of abscess in any other part. He sees no reason why, by cutting off the efferent current, the entire abdominal cavity may not be thoroughly washed out.

5. *Treatment of the Uterine Cavity after the Removal of Intra-uterine and Interstitial Fibroids.*—The patient being on the edge of the left side of the bed, the surgeon seats himself a little below the pelvis. A no. 4 fountain-syringe, previously charged with a disinfecting fluid, is suspended, or held six feet above the bed. The hose is coupled with the afferent branch of the cannula. The cannula is now introduced into the patulous os, and held in position with the left hand; this done, the nurse arranges the bed-pan and places the afferent tube (four inches long) of the cannula in it. The suction extremity of a Davidson's syringe is placed in the bed-pan, the other in a vessel at the surgeon's feet. Everything being in readiness, the stop of the hose is opened. As the fluid begins to enter the pan, having made the circuit of the cannula and the uterine cavity, the surgeon simultaneously commences with the Davidson's syringe to pump the fluid into the vessel at his feet. In this manner any amount of the fluid can be employed without once overflowing the pan and wetting the patient, an accident most annoying, not to say dangerous, since it necessitates an immediate change of clothing. As in pelvic abscess, during the passage of the fluid the current should be frequently interrupted, in order to secure its contact with every part of the suppurating surface. In a large and patulous uterus no danger need for a moment be feared. In Dr. Bixby's cases this procedure occasioned a sense of fulness, but not the slightest pain or discomfort. In one case, it was employed twice daily by himself, and at midnight an injection through the drainage-tube by the nurse, for eighteen days, menstruation being no contraindication. The quantity used was always not less than two or three quarts. He relied mainly upon the employment of a solution of carbolio acid, two drachms to sixteen ounces of glycerine, soap, and water. Though the tumour enucleated was six inches in diameter, its removal leaving an enormous suppurating surface, there was not the slightest evidence of septic poisoning, and the patient made a rapid recovery.

6. *Treatment of the Uterine Cavity in Acute Puerperal Endometritis and in Offensive Post Partum Vaginal Discharges.*—The necessity for the most thorough application of disinfecting measures at the slightest evidence of an offensive *post partum* vaginal discharge being placed beyond question, the double cannula and fountain-syringe will be found an invaluable means for the accomplishment of this end. The method of application is the same as that employed in treatment of the uterine cavity after removal of fibroids.

7. The method of application in the use of cold and astringents in *post partum* hæmorrhage, being the same, does not require a separate mention.

8. In the treatment of *chronic cystitis in the female*, the cannula is employed, with long efferent tube, as in pelvic abscess after simple puncture.*

* The curved cannula with probe-point admirably answers the purpose of a double male catheter.

Originality is here claimed for the double trocar only ; for the double cannula is mainly an improvement upon those hitherto in use. The compactness of the instruments, available for so many different and important ends, renders it useful as well to the general as to the special practitioner.

KOEBERLE ON A CASE OF OVARIOTOMY IN A GIRL AGED THIRTEEN.—Dr. Kœberle relates an interesting case of ovariectomy at an early age in the *Gazette Médicale de Strasburg* for September 1, 1875.

He remarks that ovarian tumours are occasionally met with in girls from five to fifteen years of age ; but they are generally dermoid tumours, or cysts of the parovarium, true ovarian cysts being very rare. He has operated three times on girls nearly fifteen years old ; two were cases of dermoid cyst, and in the other the organ of Rosenmüller was the seat of disease. In another case, in which he did not operate, there was a cancerous tumour in a girl eleven years old. The patient died four years afterwards of cancerous cachexia.

The subject of the present case was a girl aged thirteen. The catamenia had commenced three months previously ; the first time they were abundant, but the second time they were less in quantity, and from this time a rapid increase in the size of the abdomen was observed. Kœberle diagnosed multilocular ovarian cyst of the right ovary, and performed ovariectomy. A small incision was made ; the several cysts were gradually emptied, and the tumour, which had no adhesions, was removed. The pedicle, which was rather short, was ligatured. The wound in the abdomen was united by deep and superficial sutures ; but the former did not pass through the peritoneum. On the eighth day after the operation the patient was attacked with gastric disturbance, and had sour eructations, vomiting of greenish matter, etc.; the pulse was 120, small and irregular ; the temperature 39.5° Cent. (103.1° Fahr.). She became worse ; had violent thirst, dry skin, and cold extremities. Recourse was had to the stomach-pump, by which the gases were removed from the stomach by pouring water into it. Distinct relief was soon manifested ; and the operation was repeated three times, at intervals of ten, fifteen, and twenty hours, always with a favourable result. The patient then had aphthæ of the mouth, epistaxis, and abscesses of the ears, one of which burst spontaneously into the auditory meatus, and the other was opened by a small incision. As long as these symptoms continued, that is, for ten or twelve days, the wound in the abdomen remained stationary ; the patient, however, was convalescent on the twenty-eighth day, and returned home soon afterwards.

This is the third case in which Kœberle has used the stomach-pump with essential benefit to the patient.

REPORTS OF FOREIGN SOCIETIES.

MEDICAL SOCIETY OF BERLIN.

November 3, 1875. *Tardy Development of Hereditary Syphilis*.—Dr. Lewin showed a young man, aged or eighteen, who was born apparently healthy, and remained so up to the age of five years, when he had nodes on both tibiae, with ulceration of the superjacent soft parts, also ulcers of the pharynx and larynx, and later on of the nose and face. At present a great part of the nose and upper lip was quite destroyed, and the remainder was infiltrated and covered with ulcers. The upper incisor teeth presented the change described by Hutchinson, and lay loose in the alveoli. Beneath the right eye was a large ulcer penetrating to the bone ; the hard and soft palate, tonsils, and epiglottis were almost entirely destroyed. On both tibia were large nodes, covered with white linear cicatrices. The eyes presented the remains of parenchymatous keratitis. The patient had the appearance of a boy twelve or fourteen years old ; the genital organs were atrophied. The father said that he had become infected with syphilis during his wife's pregnancy, and had been treated with mercurial pills. In the mother, only very trifling signs of syphilis were found. There was no evidence of infection of the patient after birth. In commenting on the case, Dr. Lewin said that hereditary syphilis might manifest itself very early or very late, for the simple reason that the infection communicated from the mother to the foetus had in the latter a course similar to that in adults. In adults, there were two distinct stages of incubation : one, of two or three weeks' duration, lasted from the time of infection to the appearance of local induration and indolent bubo, which arrested the further transport of the virus ; the duration of the second stage was to the appearance of the macular exanthem, about two months. An incubation-stage of this duration had to be gone through when the foetus was infected through the mother's blood ; and it depended on the period of pregnancy at which the mother was infected, whether the child should at its birth have advanced syphilides or even visceral disease, or be born with incipient syphilitic maculae, or whether, being born apparently healthy, it should show signs of syphilis after three months. Dr. Lewin regarded cases of retarded hereditary syphilis either as instances of relapse after imperfect treatment, or as the first outbreak of an infectious germ lying latent in the organism. Of the latter, the proof was difficult ; but an example was afforded by the following case. A woman became syphilitic through the application of a strange child to her breast, and infected her husband and her own child. The husband died of

syphilis of the brain. The woman and child were cured, but after seventeen years they presented extensive defects in the pharynx and larynx. The woman had two children by a second marriage; one of these died of syphilis at the age of five and a-half months; the other, now a girl fifteen years old, remained healthy up to her sixth year, when she had syphilitic skin-eruptions, which were cured by mercury and did not reappear. Similar cases had been recorded by other authors, especially Hutchinson.—Dr. Henoch doubted whether the case brought forward was really one of syphilis. The affection of the face reminded him of lupus, and the morbid changes in the tibiae had not the syphilitic character. The evidence of tardy syphilis must be received with great caution. In the children's department of the Charité Hospital, the accounts given by the parents would often enough lead to the diagnosis of tardy syphilis; but on closer examination it was generally found that the case was one of newly acquired syphilis, or a relapse.—Dr. Lewin said that he regarded the diagnosis of syphilis in his case as only very probable, but he had no ground for suspecting acquired syphilis. Besides the history of the case, its syphilitic nature was indicated by the multiplicity of the parts affected and the backward state of growth, which did not occur to this extent in scrofula.—Dr. O. Simon said that the ulcers on the face were characteristic of syphilis and not of lupus.—Dr. Hirschberg said that the syphilitic nature of the case was specially indicated by the concurrence of parenchymatous keratitis with destruction of the fauces; he had seen this in two cases of congenital syphilis. The retarded growth also essentially supported the diagnosis of syphilis.

Trichina (?) in the Vitreous Body.—Dr. Schöller showed a woman with a live trichina (?) in the vitreous body. A similar case had not hitherto been observed. The history gave no explanation. In one eye, central vision had been already lost for some time; in the other, myopia with photopsia and other symptoms had appeared some weeks previously, and on examination a filamentous body in constant motion was detected in the vitreous body, which could only be a trichina. After the patient had been examined by several members, the discussion on the case was adjourned.

November 10. *The Diagnostic and Therapeutic Value of Tender Points on Pressure along the Spinal Column.*—Dr. Moritz Meyer read a paper on this subject. He had frequently, in cases of nervous neuralgia, convulsions, and paralysis, attended with difficulty in diagnosis and treatment, found painful points in the course of the spine, especially over the transverse processes; and the application of galvanism to these points had been followed by success. He detected these points by making equal pressure along the spine, on each side, with the second knuckle of the right index finger. Trousseau had already indicated pain on pressure over the spinous processes as an important diagnostic sign in neuralgia. Remak had also at a later period pointed out the importance of painful points along the spine; and, among other cases, had successfully treated one of neuralgia of the auricularis magnus nerve by galvanism over the second cervical transverse process, and a case of facial spasm by galvanism over the fifth—these parts being the seat of pain on pressure. Similar observations have been made by Anstie, Rockwell, and Beard, and others. As to the pathology of the painful points, it was com-

monly believed that there was a local irritation and inflammation of the nerve, and Lender regarded this as primary and essential. Braun of Rehme had lately called attention to chronic spondylitis of one or several vertebrae as a frequent cause of very various neuroses, such as neuralgia of the trifacial, occipital, and glosso-pharyngeal nerves; neuralgia of the branches of the brachial and dorsal plexuses; vertigo; epileptiform conditions; paresis of the oculo-motor nerve; and even functional insufficiency of the heart. The essential nature of the affection was believed by Braun to consist in periosteal exostosis generally affecting the lateral masses and the transverse processes on one side. In thirty-seven cases out of fifty-eight the second and third cervical vertebrae were affected, either alone or with others, and next in order came the lumbar vertebrae. The affection was generally rheumatic. These nervous phenomena, characterised as peripheral by their seat and relations, were, according to Braun, generally produced by pressure on the nerve at its exit from the intervertebral foramen, or through the peculiar anatomical conditions of the distribution of the vessels and nerves in the spinal canal. Dr. Meyer could, from observations made during several years, agree with Braun that painful points were to be detected over the spinous processes, more frequently over the transverse processes, in a very large number of neuroses. He also found, though not so frequently as Braun did, swellings at the parts or in the vicinity; regarding which, however, he could not decide whether they were due to periostitis, neuritis, abnormal muscular contraction, or glandular enlargement. Sometimes one process, sometimes another, sometimes several together, were affected, the symptoms being always in closest connection with the seat of tenderness. When the local pain disappeared or became less, the nervous symptoms also disappeared or were relieved. In using galvanism, he applied the positive pole, with a plate corresponding to the extent of the painful parts, to the spine, and the negative pole to the sternum. The strength of the current was sufficient to deflect a galvanometer twenty degrees, and the application was continued from five to ten minutes. In most cases, the neuralgia was relieved *pari passu* with the relief of the local pain, and was entirely cured when this disappeared. The cure was by no means more rapid, but generally slower, than when the constant current was applied to the peripheral end of the affected nerve or when the electric moxa was employed; but the tendency to relapse was less, if the patient and physician persevered with the treatment until the pain on pressure was totally removed. Dr. Meyer narrated a rare case of neuralgia of the penis in an officer aged twenty-five, in whom pain was detected on pressure over the spinous and transverse processes of the first lumbar vertebrae; the patient also said that for some time he had found it uncomfortable to lie on the part. Under the use of galvanism—the positive pole being applied to the lumbar spine and the negative to the sternum—there was progressive improvement for some time; then there was a standstill, and a painful point was detected at the exit of the sacral nerves on each side, immediately above the sacro-iliac symphysis (the origin of the common pudendal nerve). This part was treated in the same way; and after thirty-four applications of galvanism the patient left Berlin, much improved. Dr. Meyer also advised that careful search should be made for painful points along the spine in cases

of spinal paralysis and especially in tabes dorsalis; their treatment—perhaps because they indicated the presence of a more superficial affection of the cord—being often followed with startling results. He related in illustration a case of spinal paralysis, and one of tabes; and stated that he had obtained striking results from the treatment described, in spastic affections, often of an obstinate character, in a case of chorea with spastic affection of the median nerve, in a case of articular neuralgia from pressure of a lymphatic gland, and in several cases of writer's cramp.—Dr. Westphal agreed with the author as to the value of the treatment by galvanism; but he would call attention to the fact that pressure on the spinous and transverse processes, especially of the upper dorsal vertebrae, often produced pain (and also other symptoms, such as sudden deep inspiration), in various persons, especially females, who did not present any symptoms. In these cases the tenderness often remained some time after the removal of the pressure. The subject had been exhaustively treated by Türk. As regarded Braun's work, he thought that the author had proved too much in finding painful points in diseases of the most various kinds, including even bronchial catarrh.—Dr. Meyer did not deny the fact mentioned by Dr. Westphal; but in all his cases the various symptoms were concurrent with the tenderness on pressure in points of the spinal column; in the cases of neuralgia, the pain was felt at the vertebrae from which the affected nerves emerged, and the relief of the local pain proceeded *pari passu* with that of the neuralgia and spasm. Braun's work was of great value as calling attention to the subject.—Dr. von Adelman said that the pressure on the nerves might be produced by exudation at the point of emergence.—Dr. Westphal did not think the simultaneous disappearance of neuralgic symptoms, and of the local tenderness, a sufficient proof that they had a common origin.—Dr. Meyer maintained that his explanation was a natural one.—Dr. Weber said that Onimus had published some observations on the same subject.

Spinal Apoplexy.—Dr. Goldtammer related a case of spinal apoplexy, with the view of showing that the opinion of Charcot and other French authors was incorrect, that non-traumatic spinal hæmorrhage was never spontaneous, but always of myelitic origin. A healthy girl, aged sixteen, was suddenly attacked with violent pain between the shoulders, and, at the same time, paralysis of the legs. On her admission into hospital two hours later, she was found to have complete paraplegia, paralysis of the dorsal and abdominal muscles, and anaesthesia as high as the nipples; reflex movement was increased; there was no fever. The paralysis continued. After three or four months she had contraction, spontaneous twitchings, and greatly increased reflex excitability in the lower limbs. At the end of a year she died. At the necropsy the spinal cord was found reduced in size in a small portion of the upper dorsal region; and at this point was a rust-coloured deposit, about one third of an inch long, consisting of firm connective tissue, with crystals of hæmatoidin and brown pigment-granules; it involved the grey substance and the white columns on the right side. The cord immediately above and below the deposit was studded with granule-cells; the nerve-fibres and ganglion-cells were greatly reduced in number, atrophied, and in a state of fatty degeneration. The remainder of the cord, when hardened and examined, was found mostly healthy. Dr.

Goldtammer considered that the history of the case and the appearances found did not indicate hæmorrhagic myelitis, but rather spontaneous hæmorrhage. He was inclined to attribute the hæmorrhage to menstrual excitement. During the first days of the patient's illness (who had not yet menstruated), there was a mucous discharge from the vagina, and at the *post mortem* examination a corpus luteum was found in one of the ovaries.

November 17. *Trichina (?) in the Vitreous Body.*—The discussion on Dr. Schöler's case was renewed. Dr. Schöler said that, since he presented the patient he had abandoned the idea that the moving body was a trichina.—Dr. Fritsch had examined the patient, and believed it to be a filaria.—Dr. Schweigger doubted whether it was an entozoon at all. The appearances described might be produced by changes in the structure of the eye itself; for instance, the canalis hyaloideus might undergo vesicular dilatation. Dr. Hirschberg said that it was not a trichina; but this did not exclude the idea that it might be an entozoon. The appearance presented was very rare, and had not been described even by Von Gräfe.—Some further remarks were made by Dr. Landsberg, Dr. Schweigger, and other members.

Paralysis of the Spinal Accessory Nerve.—Dr. B. Fränkel showed a patient who, fourteen days previously, while at work, found that he could not swallow, and could not raise his right arm above the horizontal position. When the patient was presented, the paralysis was better, and paresis only was left. The phenomena of paralysis of the trapezius and sterno-cleido-mastoid muscles on the right side, and of the right part of the velum palati and the right vocal cord, were explained and demonstrated. The patient being unable during phonation to apply the velum to the posterior wall of the pharynx on the right side, a space was left through which, by means of the rhinoscope, the narrowing of the orifice of the Eustachian tube by the action of the levator palati could be observed. Dr. Fränkel regarded the case as showing that the motor fibres of the vagus nerve were supplied from the spinal accessory, and that the muscles of the palate were, at least in part, supplied by the latter nerve. There was no disturbance of sensation; the facial nerve was unaffected; the pulse was eighty, small; no changes could be detected in the respiration.

Primary Infectious Osteomyelitis.—Dr. Friedmann read a paper on this subject, the discussion on which was adjourned.

Osteomyelitis.—Dr. Senator showed the tibia of a patient, the subject of osteomyelitis, who had died after presenting symptoms which were during life regarded as those of typhus (typhoid?).

November 24. *Vaccination.*—A discussion took place with reference to petitions against vaccination, which had been presented to the Reichstag; and a resolution was passed, on the motion of Dr. B. Fränkel, in favour of the maintenance of the law of compulsory vaccination.

New Methods of investigating the Acoustic Phenomena of the Thorax.—A paper on this subject was read by Dr. H. Jacobsen.

ACADEMY OF MEDICINE IN PARIS.

January 4, 1876. *Mental Vertigo.*—M. Lasègue read a paper on mental vertigo. The word vertigo does not allow a precise definition; for sensations are

in question, of which the sufferer is the only judge. As a term of comparison, we must choose that of simple vertigo, the kind which occurs when one is at the top of a high place. Morbid vertigo also sets out from a visual impression, though the person suffering from the vertigo has only a confused consciousness of it, and closing the eyes in no ways changes his condition and sometimes increases the evil. The vertiginous sensation consists, in the first instance, in a sense of precordial distress, then in an approaching faintness, and the ground vanishes from under the feet. A secondary visual disturbance then ensues, a true obnubilation. But the dominant element of the crisis is a mental uneasiness, somewhat analogous to fear; and it is accompanied by pallor, thoracic constriction, etc. It is in vain for reason and reflection to intervene; the patient sees himself protected by a railing, he recognises the fact, but he is incapable of subduing the sensation. Two possible circumstances then present themselves; either the patient attacked by vertigo remains motionless (passive vertigo) or he exhibits a tendency to throw himself into space (active vertigo.) Mental vertigo is essentially constituted by a physical uneasiness and a mental distress which may go on to maniacal delirium. Several categories may be established. In a first category, the visual organ is clear, though varying with the patients; the sufferers are perfectly aware of the unreality of these sensations, and yet they suffer from them as if they were real. In a still more complex form, the sight of a given object, of a mirror, a gun, will bring on a crisis. The second and most frequent category comprises the cases in which the visual stage is wanting or passes unperceived, and in which the initial or dominant fact is a sensation of distress and apprehension, a groundless fear. The patient does not know what he fears, but he cannot free himself from this fear, which is so much the more distressing that it is vague and ill-defined. The intellect takes no part in this delirium; the patients are aware of its absurdity, and in the intervals of the crises, are capable of the most productive intellectual efforts. In the more complex forms, the intellect intervenes and reasons on the vertiginous sensation; but the writer only desired to call attention to the simple form.

Glanderous Leucocythemia.—M. Cohn read a paper on glanderous leucocytosis. He pointed out a hiatus which exists in the hæmatology of the glanderous affection, which he endeavoured to fill up. The method of which he makes use to number the leucocytes is only applicable to the solipeds, of which the blood coagulates very slowly. He allows the blood to subside for several hours in a graduated test-tube, at a temperature nearly at zero. The column of blood in the case of the solipeds separates into three layers; a lower one containing the red corpuscles, an upper one, almost exclusively composed of plasma, and an intermediate layer, in which are the white corpuscles, globulines, etc., heavier than the plasma, but lighter than the red corpuscles. According to the greater or less density of this intermediate layer in relation to the lower layer, the relative proportion of the leucocytes to the red corpuscles may be judged of. In glanders and farcy the layer of leucocytes increases rapidly. Parallel modifications are observed in the lymph, especially in that which is obtained from a region where some glanderous lesion is present. In fine, from the commencement, in glanders and farcy, leucocytosis,

is always present, associating itself with anemia, and its starting-point appears to be the lymphatic system.

Paraplegia from Obliteration of the Abdominal Aorta.—M. Desnos presented the pathological preparations relating to a case of paraplegia by obliteration of the abdominal aorta. The case was that of a man attacked by mitral constriction, softening of the brain, and symptoms of a dysenteric form. He was taken, after suffering acute pain from the preceding night in the left thigh, with complete and sudden paraplegia of motion and sensibility, retention of urine, blueness of the skin, suggillation, and remarkable lowering of the local temperature. He died in thirty-four hours with pulmonary congestion, hæmaturia, and intestinal flux. The appearances found at the necropsy were mitral constriction and cardiac adhesion. The aorta, otherwise healthy, showed above its bifurcation a clot, an inch long, cylindrical in shape, extending into the two common iliacs and the external iliac, and on the right into the femoral artery as far as the popliteal. He compared this rare fact with intermittent paraplegia and hemiplegia observed by veterinary surgeons in horses, and likewise in men by MM. Barth, Charcot, Gull, and Noël Gueneau de Mussy. In the latter it is due to the ischæmia produced by obturation of the aorta or its divisions by the clot. M. Desnos' case differed from the former, since the paraplegia was complete, permanent, and non-intermittent, which he explained by a complete obliteration preventing all anastomotic circulation. M. Desnos laid stress on the principal characteristics of this curious case:—1. The striking suddenness of the accidents, recalling the paraplegia of sanguineous effusion or hysterical paraplegia; 2. The excessive lowering of the temperature of the lower limbs; 3. Blueness and suggillation of the integuments; 4. Contraction of the paralysed muscles; 5. A pathognomic sign, the cessation of the arterial pulsations of the paralysed limbs.

January 11. *Rheumatism in Connection with Injuries.*—M. Verneuil read a memoir on rheumatism in its relation with injuries, of which he summarised the conclusions as follows. It is certain that injury is capable of arousing the dormant rheumatic diathesis, and even of causing its manifestations to spread to organs hitherto unattacked. It is possible that in subjects not yet attacked but only predisposed, an injury brings on the original and premature appearance of rheumatism. It is certain that the most different kinds of injuries, such as fractures, contusions, etc., have this exciting influence. All the local manifestations of rheumatism, arthritic eruptions, pain, pericarditis, cystitis, etc. may arise under this influence. Obscurities, however, still exist. How can a traumatic lesion arouse a diathesis? Why do we find such and such localisations? Why such or such a form? Why in one patient do these modifications spare the seat of injury, and in another exclusively influence the local processes? As only uncertain answers can as yet be given to these questions, some persons think it is better not to give any. M. Verneuil is not of this opinion, and develops the idea that any pathogenic influence, as cold, injury, etc., may not exhaust its action on a circumscribed point. Irradiations may set forth from this point towards other organs or to the whole system. This may be observed in a healthy patient or one of a strong diathesis. In the latter cases, distant actions and especially general disturbances are uncommon. In wounds the traumatic process progresses with less regularity;

inflammation and pain are but badly limited; the weak points of the system more easily repel the material disturbance; finally the surgical fever, more easily excited, attains a greater intensity, and is more prolonged. The provoking action of injuries on diatheses, and the choice of these diatheses for their manifestations of localities offering the smallest amount of resistance, explain the action of the principal disease in traumatism and *vice versa*.

Intermittent Broncho-Pneumonia.—M. Bourgade of Clermont read a memoir on intermittent broncho-pneumonia, frequently observed, according to him, in the middle region of France. It constitutes an incipient paludal affection, a remittent fever with bronchial and pulmonary localisations. It is more mobile than pneumonia; irregular in its progress, assuming the tertian or quotidian type. It is amenable to quinine, which effects a cure, without local treatment.

January 18. *Glanderous Leucocythæmia.*—M. Bouley pointed out the interesting nature of M. Cohn's communication. He was of opinion that the leucocytosis will facilitate the diagnosis of glanders in those cases where adequate signs are wanting. Glanders is known by three signs—chancre, discharge, and swelling of the glands—all which must be present to make it certain that there is glanders. Such at least was the opinion of veterinary surgeons until the beginning of this century. When at a later period, contagion was denied, the ravages of glanders became enormous. One of the great services rendered by Rayer to science was to establish beyond a doubt the contagious nature of this disease. It is perhaps allowable now-a-days to hope that the numeration of white corpuscles will facilitate the diagnosis in doubtful cases, which indeed are very frequent. In regiments, for instance, it happens that a horse attacked by a glanderous swelling without any other apparent sign of the disease is submitted to the application of resolvents, and when the swelling is dissolved it goes back to the ranks, where it propagates the glanders by which it is attacked. If the numeration of the leucocytes were capable in these cases of giving information, it would be a real advance. M. Bouley had had numerations made by M. Malassez on this subject which proved, in uniformity with M. Cohn's results, the existence of leucocythæmia in glandered horses.—M. Gubler expressed a fear that the bearing of a phenomenon which is very frequent and almost common-place in many chronic diseases, as in multiple suppurations, cachexias, etc., should be exaggerated. In fact, leucocytosis is too common to be erected into an element of diagnosis.—M. Chauffard shared this opinion; and leucocytosis is present in all suppurations, in small-pox, in purulent infection, and nearly all traumatisms; and also in scarlatina, measles, puerperal fever, etc.—M. Verneuil denied the constant presence of leucocytosis in the wounded as well as the hæmatic origin of pus, which, in his opinion, is far from being demonstrated.—M. Raynal regretted that, in M. Cohn's experiments, one important element had been neglected; that is, alimentation. It is well known that badly nourished animals have a large amount of leucocytes in their blood.

ACADEMY OF SCIENCES IN PARIS.

December 13. *Electric Currents.*—M. Chauveau communicated his comparative study of the electric

current, termed instantaneous, and of the continuous current, in the case of unipolar excitation. The summary of the facts he recorded is as follows. 1. In the same way as the continuous currents, instantaneous electric fluxes of very feeble intensity, more easily induce contraction with the negative than with the positive pole, but when the intensity of the current increases, the two excitations, negative and positive, always very soon become equal, and in strictly physiological cases, remain so, however far the increase of the current be pushed. Sometimes, however, a slight tendency to the inversion of the activity of the poles may be observed. Nevertheless, this tendency does not produce any very notable effect unless the nerve has undergone the perturbing influence which gives to the current of the pole the property of acting almost at once, more actively on the side of the positive pole. 2. Contraction with excitations in increasing series soon reaches a maximum value, which it cannot exceed. It is very remarkable to then see the even very considerable increase of the current, almost absolutely powerless to modify the size of the contractions. 3. The increase of the current is not, however, without influence; its action is seen, very slightly it is true, in tracings, in the form of muscular relaxation. This relaxation is so much the less sudden according as the excitation has been strong. 4. These two last characteristics are not the exclusive appanage of excitation with instantaneous fluxes. It has already been seen that they may manifest themselves exceptionally with the current of the pile; this is in the case of destruction of the spinal cord, or even of simple section of the nerves. Excitations by the current of the pile or by the induced current always give, at a certain period, tracings which, instead of differing like those of no. 1, present the most striking analogy between each other. This analogy manifests itself without any mutilation of the nervous system, if the excitation be performed on feeble frogs which are near to death. 5. The most remarkable of the characteristics of unipolar excitation by instantaneous electric fluxes is seen when the tracings obtained from intact frogs are compared with those from frogs mutilated by the section of the medulla or of the excited nerve. The former are characterised by irregularity, the second by the regularity of the superpositions exactly as with the continuous currents, and the phenomenon is due to the same cause, the partial persistence or the complete cessation of the muscular shortening after the passage of the current.

December 20. *Researches on Eucalyptus Globulus.* M. F. A. de Hartzen read a paper on this subject. The essence of eucalyptus has been examined by M. Cloëz. Besides the essence, this tree, according to the writer, contains a considerable number of remarkable substances. The brown residue obtained by distilling the alcoholic tincture of the leaves has been called eucalyptus resin; this resin contains tannin, and a great deal of fatty matter. Another resinous acid, always mixed with a little waxy matter from which it seems very difficult to disengage it, is obtained in granules. This latter acid is remarkable; it is soluble in alcohol, ether, and benzine, insoluble in acetic acid. Concentrated sulphuric acid dissolves it by forming a liquid of a beautiful carmine red, if water be added; a red matter is obtained by adding ether. If, after having macerated the leaves of eucalyptus in alcohol, they be placed in ether, it extracts from them, besides a residue of resin and

brown colouring matters, a considerable quantity of a waxy powder.

Action of Ozone on Animal Substances.—M. A. Boillot had made experiments which demonstrated to him that animal substances keep for a long time without putrefying, if five milligrammes of ozone to the litre of air be added. Two specimens placed, one in pure oxygen and one in ozonised oxygen, gave the same results in favour of preservation by ozone.

Deaf-mutism.—A note by M. Tripiet related to the pathogenesis of deaf-mutism, improperly termed congenital. Amongst the so-called congenital cases about four-fifths only became deaf towards two or three years old, and the disease made its appearance suddenly. According to the writer, this affection should be considered as an encephalic form of paralysis, of which the intrarachidean form has been described by Duchenne under the name of fatty atrophic paralysis of childhood.

T-shaped Nerve-tubes.—M. L. Ranvier presented a note on the T-shaped nerve-tubes, and their relations with the ganglion-cells. Minute experiments made by the writer have demonstrated to him that almost all the nerve-tubes which set out from the ganglion-cells, instead of preserving their individuality in directing themselves towards the centre or towards the periphery, presented T-shaped anastomoses with the tubes coming from the posterior roots.

REVIEW.

Charité-Annalen. I. Jahrgang, (1874), Berlin, 1876.

We have received the first volume of a new series of the Berlin Charité Hospital Reports. The former series, after having been published quarterly for eighteen years, was discontinued in 1868. The report now appears in the shape of one annual volume, which, the preface tells us, gives its readers 'a review of the advances made in the investigation and treatment of disease, of the results of surgical operations, of the data of pathological anatomy, in short of the performances of the establishment in all the departments of medical knowledge.' The present volume is edited by Dr. Mehlhausen, and contains a carefully arranged statistical table of the cases treated during the year, showing the results in each branch of medicine, and between five and six hundred pages of essays and reports of cases by various members of the staff. The volume closes with a paper by Professor Virchow on the method of making *post mortem* examinations, which for thoroughness in detail we commend to the notice of British pathologists. It is notorious that our waste of pathological material is enormous from the want of inclination or time to investigate the cases more fully; we fear that there is no remedy for this until hospitals insist on the pathologists devoting the whole of their time to their department, and to do this they must be paid proportionately. The pathologist in many of our hospitals is the youngest member of the staff, active, energetic and ambitious, anxious to place himself in the front ranks of his profession and to bring his name prominently before the medical world. For this purpose he finds the *post mortem* theatre most useful, affording him, as it does, ample material for specimens to lay before the Pathological Society; but he prefers taking various clinical appointments at the minor hospitals to devot-

ing himself to the arduous task of minute pathological investigations; or if, here and there, one be found to do good work giving promise of much from his future exertions, just as his experience is ripening and he has acquired some degree of manipulative skill, he is translated to the chair of an entirely different subject, and is succeeded by another youthful competitor for the honours of the Pathological Society. On the whole, we find that these reports do not differ materially from those published in this country; and though the volume contains much worth perusal, it has in it no paper remarkable for the originality of its thought or the novelty of the facts disclosed; possibly on the continent, as here, such publications are not much in favour for introducing new views to the profession. In justice to the editor, whose labours in compiling the statistics have not been light, we must give a full share of praise to the excellent arrangement and general style of the work, and we see reason to believe that the series will become a valuable addition to our annual medical literature.

RECENT FRENCH BOOKS.

Published by Adrien Delahaye.

Traitement préservatif et curatif des sédiments, de la gravelle, de la pierre urinaires, et de diverses maladies dépendant de la diathèse urique, par le docteur L. Aug. Mercier. Paris, 1872. Un volume in-12. Prix: Broché, 7 fr.; cartonné, 8 fr.

Les rimes de l'officine, par E. Genèveux. In-12. Prix: 2 fr. 50.

Published by J. B. Baillière and Sons.

La femme-médecin, par G. Richelot, docteur en médecine. Paris, 1875. E. Dentu, libraire-éditeur, Palais-Royal, 17 et 19, galerie d'Orléans. Prix: 2 fr.

Leçons cliniques sur les maladies mentales professées à la Salpêtrière par le docteur Auguste Voisin, médecin de la Salpêtrière, avec photographies, planches lithographiées et figures intercalées dans le texte. Paris, 1876. Grand in-8 de 196 pages. Prix: 6 fr.

Assainissement des régions chaudes et insalubres, par Régulus Carlotti, président de la Société locale des médecins de la Corse, membre de l'Académie nationale agricole et manufacturière, vice-président de la Société météorologique du département, et chevalier de la Légion d'honneur. Paris, 1875. In-8 de 87 pages. Prix: 2 fr.

Exposé théorique et pratique des maladies vénériennes. Nouvelle doctrine proscrivant les injections et le mercure, par le docteur Ch. G. Saint-Martin de Laplagne, suivie de 50 aphorismes, d'une histoire naturelle de la blennorrhagie, de la manière de se traiter soi-même, de l'examen des fraudes et délits dans les relations sexuelles. Paris, 1876. 1 vol. in-12 cartonné de 252 pages. Prix: 5 fr.

Leçon sur la structure et les maladies du système nerveux, par M. J. Luys, médecin de la Salpêtrière. Prix: 3 fr.

De l'emploi des préparations arsenicales dans le traitement des maladies du cœur, par M. Louis Bouyer, de Saint-Pierre de Fursac (Creuse). Prix: 1 fr.

Published by Germer-Baillière.

Large communication entre la veine porte et les veines iliaques droites, par Carlo Giacomini, professeur à la Faculté de médecine de Turin. Mémoire traduit et annoté par E. Labbé et A. Aubeau. Prix: 1 fr. 50.

Published by G. Masson.

Recherches expérimentales sur le rôle thérapeutique du suc concentré de cresson dans le traitement de la phthisie pulmonaire et des affections de la peau, par B. Dupuy.

MISCELLANY.

PROFESSOR CALORI has been nominated Rector of the University of Bologna.

A NEW code of regulations for medical education and examinations, issued by the Italian Minister for Public Instruction, is published in the *Giornale Veneto di Scienze Mediche* for January.

DEAF-MUTISM.—The *Journal des Sages-femmes* reports the case of a deaf and dumb woman, married to a deaf and dumb husband, who was admitted to the lying-in hospital for her confinement. She had had five children born dead, and a sixth which survived, and speaks and hears perfectly well.

A CONVOCATION of the University of London was held on January 17, at which, after a long discussion, a resolution was passed affirming the desirability of obtaining a new charter, and declaring that no such charter would be acceptable to convocation which did not enable the University to grant degrees to women.

LOUISE LATEAU.—The *Courrier de Bruxelles* states that Louise Lateau is dying. The usual phenomena of her ecstasies have appeared but she is not able to leave her bed. Medical aid has been called in, but without avail. The *Indépendance Belge* comments on the latter fact, and is astonished that the aid of mundane physicians should have been sought; profanely inquiring why the aid of the Virgin Mary and the curative effects of the Lourdes water have not proved sufficient. The same journal suggests that the unfortunate stigmatic may perhaps be a victim to the trickery of which she has been an instrument, a martyr to speculation on supernaturalism and superstition.

A GRATEFUL PATIENT.—The Zoological Garden at Dresden is fortunate in the possession of specimens of the larger simian races, which as a rule are acclimatised with great difficulty in our latitudes. Amongst these specimens is a female gorilla, which has been suffering for some time with an abscess of the throat. This animal astonishes and amuses the visitors and keepers by pointing out the seat of the trouble with her paw, and receives her doctor, the veterinary surgeon of the establishment, with the most lively manifestations of pleasure and gratitude. A striking resemblance will be observed in the behaviour of Madam Gorilla and the higher developments of the feminine gender, who also are generally not averse to the bland sympathy and consolation of 'my medical attendant.'

'THE THINGS THEMSELVES ARE NEITHER RICH NOR RARE,' ETC.—An unfortunate lunatic, who died in the Prestwich Asylum a short time ago, seems to have lived neither wisely nor well. A *post-mortem* examination led to the discovery of no fewer than 1,841 articles in his inside—viz., 1,639 shoemaker's sparsables, six 4-inch cut nails, nineteen 3-inch cut nails, eight 2½-inch cut nails, eighteen 2-inch cut nails, forty ½-inch cut nails, seven ¾-inch cut nails, thirty-nine tacks, five brass nails, nine brass buttons, twenty pieces of buckles, one pin, fourteen bits of glass, ten small pebbles, three pieces of string, one piece of leather three inches long, one piece of lead four inches long, and one American pegging awl—the total weight being 11 lb. 10 oz.

CHOLERA AND THE MECCA PILGRIMS.—The ravages caused by the cholera in Syria, during the last year, induced a fear lest the Syrian pilgrim should introduce the disease into Arabia, after their voyage to Mecca. According to the *Akhbar*, however, the public health of the Hedjaz is perfectly good, owing to the precautions taken at the places where the pilgrims disembarked, and especially to the interdiction placed on this voyage by some governments. Thus the arrivals of pilgrims at Djeddah have been relatively small, and amount from July 22 to

November 1 to 12,369 pilgrims, amongst whom were representatives of all Oriental nations from Mogrebins to Japanese. The pilgrims journeyed in small groups, of which the successive transport necessitated the employment of thirty-five steam-boats. The sanitary administration of Egypt has just promulgated a special regulation for the transport of pilgrims going to the Hedjaz by way of Egypt.

ZOOLOGICAL STATION AT NAPLES.—The Cambridge Board of Natural Sciences Studies report that the period of three years for which the University agreed to pay 100*l.* a year towards the expenses of Dr. Dohrn's Zoological Station at Naples will expire next year, and they have had under consideration the expediency of recommending a continuance of the grant. For the sum of 100*l.* the University has hitherto had the exceptional privilege of occupying two of the large working tables. Dr. Dohrn is unable to continue the offer of accommodation on the same terms, but offers one or two tables at 75*l.* per table. The Board, considering the claims upon the Worts' Travelling Bachelors' Fund, do not think it right to charge that fund with two tables at the increased price; and therefore recommend that one table be retained by the University for five years at the rate of 75*l.* per annum. The Board have reason to believe that very valuable work has been done by nominees of the University at the station, and the Cambridge Museum enriched by important specimens procured from it. Mr. T. W. Bridge, scholar of Trinity, and Mr. J. F. Bullar, of Trinity, have been nominated by the Board of Natural Sciences Studies to study at the Zoological Station, Naples, until July 1876.

FEMALE MEDICAL STUDENTS IN RUSSIA.—The *Semaine* of St. Petersburg publishes the following minute statistics respecting the medical and surgical courses for women in that city. The number of pupils in the two courses during the scholastic year 1874-5, amounted to 171, of whom 102 were of noble birth, 17 belonged to the commercial classes, 14 were of the shopkeeping class, and 12 were clergymen's daughters. They were divided, as to their religious belief, into 131 of the Greco-Russian Church, 23 Jewesses, 12 Roman Catholics, 3 Lutherans, and 1 Armenian. Out of the number, 23 were married women, and 53 had brought with them diplomas from private tutors. The professors of the Academy of Medicine and Surgery continued to be highly satisfied with the application shown by the female classes. Many of the pupils remained far into the night at the chemical laboratory and the dissecting-room. During the visits to the hospital, the pupils showed a knowledge of the progress of the diseases of the patients which astonished the professors. It frequently happened that they spent the whole night in attendance on a serious case.

DR. SAMUEL GRIDLEY HOWE.—Dr. Howe of Boston, the patient and pains-taking instructor of the blind, in which capacity he has achieved a reputation far beyond the limits of his native city has lately died. In 1832 he opened the Perkins Institution for the Blind, at South Boston, threw himself into this work with great ardour, and during a long period of service has contributed more, perhaps, than any other man to the improvement and happiness of an unfortunate class. He has the honour of being the inventor of the method of printing in raised letters, one of the greatest boons ever conferred upon the blind, and by his words and writings has done much for their education all over the world. He has taken a prominent part in the training of the idiotic and the feeble-minded, and was the principal of the school organised in 1851 for improving the condition of those classes. Dr. Howe's labours at the blind asylum are full of interest, and have been the admiration of many distinguished visitors to the asylum. The case of Laura Bridgman alone was enough to have established his reputation in his special field, though this was but one bright feature in a life's work well and faithfully accomplished.

The London Medical Record.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

CHARCOT ON THE LOCALISATION OF CEREBRAL DISEASES.

In a course of lectures delivered last year in Paris (*Le Progrès Médical*) Professor Charcot placed before his hearers a general exposition of the facts now established bearing upon this interesting and important part of medical diagnosis.

In his first lecture, after pointing out the importance of his subject, and referring to the assistance it had received from the labours of his friend, Dr. Lépine, he gives a brief account of the anatomical structure of the encephalon, illustrating it by a diagram of a vertical section of the brain, made at the level of the corpora albicantia.

After naming the different parts of grey and white matter thus displayed, the lecturer describes the histological structure of the grey matter of the convolutions, according to the statements of Meynert, Luys, and Henle. He also refers to the special labours of Betz upon the modifications of structure in different convolutions, more particularly to his observation that the convolutions lying anterior to the fissure of Rolando are characterised by the predominance of large pyramidal cells over those of globular form; while in the convolutions lying behind that fissure, and comprising the sphenoidal and occipital lobes together with the mesial portion as far as the anterior edge of the quadrate lobe, the large cells are rare relatively to the granular or round cells. In each of these regions, there is a special territory deserving closer attention. In the posterior region the nerve-cells are of large size, but the prolongations of protoplasm are few, and that rising from the base is directed horizontally and sometimes connects two cells with one another; this arrangement is observed in the cuneus, the posterior half of the quadrilateral lobe, all the occipital lobe, the two superior sphenoidal, and the connecting convolutions. According to Betz, this region is that of the sensorial functions.

In the anterior region, the part deserving special attention is that characterised by the presence of pyramidal giant-cells, or motor cells *par excellence*. It comprises the anterior frontal convolution in its whole length, the anterior parietal convolution in its upper extremity, and lastly, a part to be studied under the name of the paracentral lobe; it is more especially in this last-named lobe that the giant-cells are most numerous. They are found in the brains of all species of monkeys; and Betz, in the dog, has observed these same cells in the regions designated by Fritsch and Hitzig as motor centres, while they do not exist anywhere else. It is also true that in the monkey the distribution of these giant-cells is restricted to those convolutions in which Ferrier has shown the existence of motor points. He then recalls a case, published by Sander in the *Centralblatt*, 1875, of a child affected by in-

fantile paralysis since its third year, which died at the age of fifteen. All the limbs were more or less atrophied, but especially those of the left side. At the necropsy, the usual lesions of the cord were recognised, but, in addition, a careful examination of the brain led to the discovery that the two ascending convolutions were much shorter than natural and not convoluted, while the paracentral lobe was quite rudimentary, and contrasted with the other convolutions which were perfectly developed. Moreover, these lesions were more marked in the right hemisphere than in the left; corresponding with the spinal lesions, which were more marked on the left side. Unfortunately, the state of the nerve-cells does not seem to have been examined.

M. Charcot further remarks that in the brains of very young children these giant-cells are very few; and, again, M. Rouget has remarked that in new-born puppies excitation of the regions corresponding to the psycho-motor centres produces no corresponding muscular movement, while some time after birth these points become excitable; thus making it reasonable to infer that they develop with the age and in consequence of functional exercise. It may here be asked whether such a process of development may not possibly be the means by which such centres are replaced under the influence of functional excitement, when they have been destroyed by some lesion?

The lecturer next proceeds, after these preliminary anatomical considerations, to point out the fundamental conditions indispensable for resolving the problems relating to cerebral localisation in the diseases of the human subject. These are:—

1st. A good clinical observation, made as much as possible by the light of data supplied by experimental physiology:

2nd. A regular necropsy, perfectly made.

He then proceeds to ask and answer two questions:

1st. What are the alterations of which the encephalon is susceptible?

2nd. What are the general anatomical conditions which govern the development and mode of distribution of these lesions?

In order to simplify this inquiry, he establishes a parallel between the great divisions of the cerebro-spinal axis, viz., 1. the spinal cord; 2. the medulla; 3. the brain proper. He then goes on to point out that one great fact governs the pathology of the spinal cord, viz., the existence of so-called systematic lesions; meaning by this, lesions which systematically circumscribe themselves within certain definite regions of the cord—for example, those restricted to the anterior cornua of grey matter, producing atrophy of muscles, or those limited to the lateral columns, producing paralysis with a tendency to contraction. Such systematic lesions are also found in the medulla, the pons, and the cerebral peduncles themselves; but above this point this mode of pathological alteration ceases to exist. Indeed, it appears that in the brain proper it is the arrangement of the vascular system which governs its pathological anatomy; and this leads us to inquire what are the normal conditions of that system, and brings us back to certain anatomical considerations.

After referring to the arrangement of the arteries at the base of the brain, M. Charcot says that the posterior cerebral arteries supply the sphenoidal and occipital lobes; the anterior cerebral arteries supply part of the anterior lobes, and a large extent

of the internal surface of the hemispheres, as well as the subjacent regions of white matter; while the middle cerebral or Sylvian arteries distribute themselves over the inferior frontal and ascending convolutions, the parietal lobe, and dip into the subjacent parts of the medullary centres, and, moreover, furnish branches to the optic thalami and corpora striata. Each of these three principal arteries gives rise to two different systems of secondary vessels: the first, called the system of cortical arteries, being distributed in the thickness of the pia mater, and dividing to supply the grey and white matter of the convolutions; the second or central system supplies the ganglionic centres. He then proceeds to describe, after Duret, the more minute arrangement of the blood-vessels. He refers also to the labours of M. Heubner, whose conclusions are opposed to those of Duret as to the anastomosis between arteries of different regions, and adds that M. Cohnheim supports M. Duret's opinion, saying that the arteries of the brain are, as a rule, terminal arteries, as are those of the spleen, the kidney, the lungs, and the retina.

As the parts supplied by the branches of the Sylvian artery comprehend the famous psycho-motor centres, it is necessary to describe their arrangement. There are four principal branches. The first supplies the third frontal convolution. On many occasions this convolution has been the seat of softening limited to itself. A woman, F., was admitted to the Salpêtrière attacked by aphasia; there was no trace of other paralysis, either of motion or of sensation. Aphasia in this case was the sole symptom, and the atrophy of the third convolution was shown by *post mortem* examination to be the sole corresponding lesion.

The second branch supplies the ascending frontal convolution. The third supplies the ascending parietal convolution, and the fourth the gyrus uncinatus.

It is to be observed that the second and third branches supply those two convolutions which, according to the experiments of Ferrier upon monkeys, are the seat of the motor centres of the limbs; the ascending parietal convolution being the centre for the movements of the upper extremity and in part for the lower also.

In a case within the lecturer's knowledge, this convolution was replaced by a depressed yellow patch, and the ascending frontal convolution was manifestly atrophied; now, although the optic thalami and corpora striata were perfectly intact, complete and permanent hemiplegia existed in both upper and lower extremities of the opposite side. On the other hand, in a case of destruction limited to the quadrate lobe there was no trace of corresponding paralysis; and in another case, implicating a large extent of the inferior surface of the sphenoidal lobe, there was no trace of hemiplegia during life.

The anterior cerebral artery furnishes three principal branches: the first supplies the two inferior frontal convolutions; the second supplies the convolution of the corpus callosum, the corpus callosum, the paracentral lobe, the first and second frontal convolutions, and, lastly, the superior extremity of the ascending frontal convolution; the third branch supplies the quadrate lobe.

The posterior cerebral artery is seldom the seat of thrombosis or embolism; it divides into three branches, which supply respectively (1) the gyrus uncinatus, (2) the convolution of the hippocampus,

the third temporal and the middle occipito-temporal convolutions, (3) the occipital convolutions, the hippocampi major and minor, and the quadrate lobe.*

(To be continued.)

TWO CLINICAL LECTURES ON THE CAUSES, THE PREVENTION, AND THE CURE OF LACERATION OF THE PERINÆUM. BY WILLIAM GOODELL, M.D., CLINICAL PROFESSOR OF DISEASES OF WOMEN AND CHILDREN IN THE UNIVERSITY OF PENNSYLVANIA, ETC.†

LECTURE II.

While warmly advocating the primary operation, I have not found it on the whole so successful as the secondary. Thus, by the former I have had thus far two failures; by the latter, none. This is said to be owing to the irregular surface of the rent, which prevents exact coaptation; and to the lochial discharges, which insinuate themselves between the surfaces of the wound and hinder union. My cases of failure were, however, dependent on other causes. In one, the woman, in a fit of mania, jumped out of bed to throw herself out of the window, and, of course, tore out the stitches. In the other—to which I was called by the attending physician—a violent diarrhœa set in on the third day, resulting in a recto-vaginal fistula, which I afterwards succeeded in closing. If upon removing the stitches you find no union, do not give up in despair; but try to promote healthy granulations by keeping the parts sweet and clean, and by placing in the fork of the wound a pledget of lint dipped in a solution of carbolic acid just strong enough to produce some tingling. By this means you may yet hope to save your credit by getting a bridge of granulations thrown over the anal gap, or more or less of very good union.

Supposing you utterly fail to get union by the immediate introduction of sutures, what is next to be done? Wait until the wound has cicatrised, and the woman has wholly recovered from her lying-in. Then reconstruct her perinæum by the operation which I am now about to perform upon the patient whom you saw at my last lecture.

She is in as fair health as a woman thus afflicted can be. Had she a diarrhœa or a cold, I should postpone the operation; for one untimely movement of the bowels, or the succussions from incessant coughing or from sneezing, would interfere with union. Were she nursing, I should, both for her sake and for that of the child, advise delay until the child is weaned. Nor should the operation be performed just before a monthly period, but a few days after. Early yesterday morning she took a full dose of oil, and this morning one grain of opium in order to restrain the bowels from further action. To avoid ether-vomiting, she has eaten a very light breakfast.

The instruments needed for this operation are as follows: an ordinary scalpel and a pair of scissors curved on the flat; a long-handled rat-toothed forceps, with a hole in the end of the handle to serve as an adjuster; half-a-dozen *serres-fines*; a few perforated 'number-one' shot, and a shot-compressor;

* For a short summary of Duret's anatomical observations, English readers are referred to an abstract of his papers in no. 93 of the *Journal of Mental Science*, for April 1875, p. 136 *et seq.*

† From the *Philadelphia Medical Times*, November, 1875.

a self-retaining catheter, one blunt-edged perineal needle, with an eye near its point; silver wire, several surgeon's needles with varying curves, and a needle-holder. All these instruments are, however, not absolutely essential. At a pinch, a pair of flat-nosed jeweller's pliers will answer all the purposes of a shot-compressor or of a needle-holder. An ordinary flexible catheter secured in the urethra by strips of adhesive plaster makes a very good substitute for the self-retaining catheter. Instead of a special forceps with an adjusting hole in its handle, you can use an ordinary dissecting-forceps; while the tongue-tie slit in the handle of a grooved director makes an excellent adjuster. I may also add that perforated shot are sold so cheaply by instrument-makers, that to purchase a shot-punch will be a needless expense.

Deeply etherised, our patient will now be brought in the lithotomy position to the end of this table, which fronts a good light. Her knees are supported by these two gentlemen, who also place the fingers of the free hand on each side of the vulva, and stretch it open. A third assistant attends to the etherisation, whilst a fourth looks after the sponges and instrument. Of course, one can operate with but three, or even with two, assistants, as has been my experience in the country; but it is far more satisfactory to have the aid of four. The first thing now to be done is to clip off the hairs round the rent, the next to pare its cicatrised edges. But if I should first denude the lateral surfaces, the blood would trickle down over the rectal portion and obscure it. I therefore introduce two fingers in the bowel, so as to put the over-lying and rugous mucous membrane on the stretch, and begin the operation by trimming off the rectal edges of the rent, and by snipping off with the curved scissors a thin film of its mucous surface. This dissection is continued until the raw surface extends for at least an inch and a half up the posterior wall of the vagina. Partly by snipping with the scissors and partly by paring with the knife, I now denude the right side of the rent. By encroaching inwardly on the mucous surface of the vagina, and outwardly on the cutaneous surface of the nates, there is gained on the labium a raw surface a little longer and broader than the glazed cicatrix of the original perinæum—say about an inch in breadth—and extending upwards to a point about half an inch below the meatus urethræ. The oozing of the venous blood, you see, is quite free; and this is usually the case in all operations of this kind, because the parts are vascular, and the veins valveless. Close to the lower edge of the raw surface two small arteries are springing, but I shall not tie them, lest the ligatures should act as foreign bodies, and prevent union. By nipping each one with a *serre-fine* I stay the bleeding. In all operations in which you wish to avoid the use of ligatures, you will find these little spring-clips of great service. I shall leave them on until the wound is ready to be closed.

One side of the rent being now made raw, its exact counterpart on the other side remains to be freshened. To gain accuracy in this, my assistants will for a moment remove their hands from the vulva, while I, by pressing for an instant the nates firmly together, get on the left side an exact blood-print of the raw surface of the right side. This manœuvre may not succeed if the *serres-fines* lie in the track of the wound, and you will then be guided by the eye alone. In denuding the left side I find it needful to use but one *serre-fine*. The cutting part

of the operation is now finished, and results in a large raw surface, with symmetrical outlines, wider on the posterior wall of the vagina than on the labia. This form of raw surface gives greater strength to the parts, and imitates nature; for the natural perinæum is wedge-shaped—thickest at the cutaneous surface where the vulva and anus recede from each other, and thinnest where the vagina and rectum approach each other to form the recto-vaginal septum. When the recto-vaginal rent is a bad one, the denudation of the septum should be extended a little higher up the vagina. When, also, the rectum is much relaxed, and its mucous lining prolapses, it will be well to prolong the vivification of the cutaneous surfaces on each side downward to a level with the lower margin of the anal opening. The wound is now to be closed; but before doing so, let me carefully sponge every part of the bleeding surface, to see whether any portion of mucous membrane or of skin has escaped the knife or the scissors. The recognition of such points is by no means as easy as you may think. Here, for instance, at the junction of the rectal and of one lateral portion of the wound, I find a suspicious-looking point. Whether it be a ridge of raw surface or an islet of mucous membrane, I cannot tell, and therefore, to be on the safe side, snip it off. The sutures are next to be passed; and since, gentlemen, upon the manner in which they are introduced will your success depend, I ask your close attention.

The perineal needle is entered unarmed on the left buttock, nearly half an inch below the lower angle of the wound, and about an inch from its margin. For the first inch it is plunged in directly backward. Its point is then turned towards the vagina, and made merely to protrude as far as its eye on the mucous membrane near the middle of the posterior vaginal wall, just above the uterine edge of the raw surface. The needle being now threaded with a piece of silver wire about a foot in length, and withdrawn, of course brings back with it the wire. It is then unthreaded, and entered at a corresponding point on the cutaneous surface of the other side, and the eye made to protrude on the mucous membrane at a point quite close to its fellow. The vaginal end of the wire is now passed through the eye of the needle, and, as I withdraw the latter, is left in its track. Thus you see that this first and most important stitch makes the whole circuit of the rectal portion of the wound like the string of a purse. If tightened, it will purse up the tissues from below upward, and secure complete coaptation of the anal margins of the rent. Any other method of passing the first stitch is very liable to result in a recto-vaginal fistula, which is not easily closed up.

Remember, then, this golden rule in perineal surgery: Whatever the degree of laceration, and whatever the nature of the operation,—namely, whether primary or secondary,—the point of entrance and of exit of the first suture should always be fully half an inch below the lowest angle of the wound. When the sphincter ani is torn, as in the case before us, these points will be on a level with the lower verge of the anal opening, or even a little below it. In a like manner, three other sutures are introduced at points about half an inch apart, and about an inch from the cutaneous margin of the lateral raw surfaces. In each instance the needle is at first pushed in directly backward, and then made merely to protrude on the mucous surface just above the line of denudation. As fast as each suture is placed, its ends are

loosely twisted together, so as not to become entangled with its fellows.

Although this long-handled perineal needle is the handiest instrument for the introduction of these deep sutures, it is by no means indispensable. An ordinary surgeon's needle two and three-quarters of an inch long, and slightly curved, will answer the purpose well, if held in the bite of a needle-holder. Armed with the wire, it should be passed through one side first, and made to emerge wholly in the vagina. Being disconnected from the wire, it is now threaded with the loop-end of a double silk ligature, and entered on the cutaneous surface of the other side, and made to emerge as before into the vagina. The needle being now removed, the vaginal end of the wire suture is passed through the loop, and bent over it. As the latter is withdrawn the wire follows it, and is pulled through. For the convenience of right handed physicians who are helpless with the left hand, some one has devised a left- and right-needle. The one which I show you is for the right cheek of the buttock, and can be manipulated by the right hand of the operator. Whatever the kind of needle used, its cutting edges should be blunted; otherwise a smart hemorrhage may take place from the suture-tracks, or an hæmatocele and abscess form in these very vascular parts. From such a cause, also, I have seen a good deal of ecchymosis on one cheek of the buttock.

I now remove the three *serres-fines*, and, as you see, the arteries have stopped bleeding and do not need to be tied. The general oozing of blood is, however, still free, and this I shall try to staunch by directing upon the wound a stream of ice-water through the nozzle of a syringe. The cold douche checks it somewhat, but not fully; and this is my very uniform experience in this operation. Fortunately, the adjustment of the stitches will invariably control it; indeed, gentle traction on the ends of the wire sutures at once stops all oozing. After carefully sponging away the blood, I pass the ends of the lowest suture through the hole in the handle of the forceps, and, while drawing upon them, firmly push the latter down upon the skin. This manœuvre brings the parts together very accurately, 'sets' the wire, and straightens out any crinkle in it. The adjuster being removed, a perforated shot is slipped over the ends of the wire. This is next seized in the jaws of the compressor, and, after being firmly pushed home, is clamped. Since the success of the operation depends mainly on this suture, and since the strain on it is greater than on any of the others, I shall bead the wire with a second shot, and clamp it over the first one. Each suture is in like manner secured by a single shot, and the free ends of the wires snipped off. One finger in the rectum and another in the vagina inform me that the wound is accurately closed. Carefully examining the cutaneous edges of the wound, I find between the deep stitches a point where two surfaces of skin seem doubled over upon each other, and one where two raw surfaces are everted from each other. With the forceps I gently unfold the former, and bring together the latter, and then secure the raw surfaces in apposition, by passing, with an ordinary curved needle, a superficial suture at each point. When perfect coaptation is gained by the deep sutures, the superficial ones are wholly needless. I do not know that the success of the operation depends upon the use of the shot-clamps. The mere twisting together of the wires is warmly advocated by some operators. But

I have been so lucky with the former method—one which I learned from your distinguished teacher of surgery—that I shall be in no haste to change it.

The operation is now ended; but before removing our patient to her bed, let me empty her bladder. While withdrawing the catheter, I kept my finger closely applied to its mouth, so that the few drops of urine retained within it shall not escape and trickle over the wound. I also fold up a soft napkin, put it between her knees, and bind them loosely together.

Upon the after-treatment also will the success of this operation greatly depend. In order that no drops of urine may come into contact with the wound, and by irritation prevent union, I shall have her urine drawn off. After the fifth day she may turn over on her hands and knees, and make water in that position. But the pain is so much increased by such a movement, that the catheter will generally be needed until the sutures are removed. Twice a day is usually often enough; but on several occasions I have met with an irritable bladder which urgently called for far more frequent evacuations. Should such a complication present itself, or should the nurse be unable to pass the instrument, or should your patient live at a distance, a winged catheter, or a double curved self-retaining one, may be worn. In order to prevent injury to the bladder, it should just pass the neck and not touch the fundus. By a piece of India-rubber tubing drawn over its mouth, the urine can be conducted into a vessel on the floor, and the bed kept dry and sweet. In introducing the catheter, one of two modes may be adopted. The physician either may pass it by the touch, with the woman lying on her back or on her side; or he may unbind her knees, slightly separate them, and introduce the instrument by the eye. The self-retaining catheter with its India-rubber tube should be daily removed, taken apart, and carefully cleansed. Otherwise urinary deposits will clog it up, or roughen its exterior surface, and may even produce cystitis. For instance, last year I was called into the country to operate on a perineal rent, which extended nearly one inch up the recto-vaginal septum, and was, as usual, caused by the use of the forceps. After the operation a self-retaining catheter was introduced, which, through some misunderstanding on the part of the attending physician, was not removed. At my next visit, a week later, I found, to my dismay, the lady in great pain, the catheter and tubing wholly clogged up, and the contents of an over-distended bladder dribbling away over the perinæum. On cutting the sutures, to my great surprise and great delight I found that, in spite of these drawbacks, perfect union had taken place. But for two months thereafter the lady was annoyed by so distressing an attack of cystitis, that she described herself as having fallen from the frying-pan into the fire. She ultimately got perfectly well; but it taught me a lesson which I wish to impart to you.

Our patient's bowels must also be kept locked up. Enough opium to ease the painful tension of the sutures—say one grain every four or every six hours—will probably be ample. Sometimes, after this operation, your patient will be annoyed by painful flatus. If it do not yield to teaspoonful-doses of the fluid extract of valerian, a flexible catheter should be carefully insinuated up into the rectum. Occasionally the wind will escape involuntarily; and, if your patient be fat, or lying on her back, she will think that she breaks it from the vagina, and will insist upon it that the operation is a failure. This happened

not long ago to one of my private patients. It gave her and me much needless anxiety, for when the sutures were cut, I found that perfect union had taken place. Here are the shotted sutures which were used in her case. The one beaded by two shot lay next to the anus; it is the longest one, and measures just 3.75 inches. I exhibit it especially to show you how long it is, and how much flesh it must have enclosed in its loop.

The only local dressing needed by our patient will be a pledget of lint dipped into cold water. On the third day, but not earlier, lest the process of immediate union should be hindered, I shall have the vagina washed out twice daily by a weak solution of carbolic acid, or by a claret-and-water-coloured solution of the permanganate of potassium. These injections will soothe the parts and correct the bad odour of the discharge. She will be enjoined to keep very quiet in bed. She need not rigidly lie on her back, but may, with help, turn over on her side. Her diet will be milk, toast, eggs, and broth.

Without reference to any specified time, the sutures will be removed as soon as they become loose,—that is, from the seventh to the ninth day. I shall not first snip all the sutures and then proceed to remove them, but shall cut one at a time and draw it out before touching the others. I shall also begin at the lowest wire,—the one next to the anus,—so that during the removal of this the most important one of all, the parts may be firmly braced together by the upper sutures. Its fellow will next be cut and drawn out, and so on until all are removed.

On the tenth day, or on the twelfth, if the line of union be weak, small doses of a saline cathartic or teaspoonful doses of castor-oil will be administered to our patient every four hours, until she feels an urgent inclination to go to stool. Then, in order to insure the liquefaction of the contents of the lower bowel, an injection of soap-water will be given. She will also lie on her back, with a shovel bed-pan under her person, and be instructed to restrain all tenesmic efforts. Should hardened fæces over-distend her rectum, the nurse will break them up either by her finger, a hair-pin, or the handle of a spoon.

At my next visit I shall carefully inspect the parts, to see whether the wound has been at all torn open by over-stretching. Should, unfortunately, a fistulous opening in the recto-vaginal septum remain, it may, if small, be treated by an application of the *acetum cantharidis* or of fuming nitric acid, followed by coaptation with *serres-fines* or with sutures, and, these failing, by the actual cautery. If the fistula be of any size, no treatment will probably be successful other than that of cutting through the united portion and of doing the original operation over again. Although the operation may be a successful one in respect to the union of the raw surfaces, yet usually the control over the sphincter does not at once return; sometimes, though rarely, it is not wholly regained. You must, therefore, be careful how you commit yourself to the promise of a rapid or a perfect cure.

After the bowels have been thoroughly opened, they should be again locked up for four or five days more, and then be daily kept open by a mild aperient. The patient should have her knees bound together, and stay in bed for at least two weeks, and for a week longer should not go out of her room. During this time she should walk about but little, and keep her knees close together. Such precautions

are necessary, in order that the newly united tissue may not become relaxed by over-stretching.

In your text-books you will find described and illustrated different operations for the restoration of the functions of the sphincter ani, and for the reconstruction of the perinæum—such, for instance, as the quill-suture, division of the sphincter, etc. But I have restricted you to one which recommends itself not only for its simplicity, but also for the very remarkable success which attends it. It, further, is an operation which, in conjunction with the amputation of the cervix uteri, you will find very valuable for prolapse of the womb, when the perinæum is anatomically whole but functionally imperfect.

EBERTH ON DISEASES DUE TO INFECTIVE MYCOSIS.

In the number of *Virchow's Archiv* for December 1875, is a paper by Eberth, which is occupied with the minute detail of three cases, all of them supposed to have originated in an abnormal local development of micrococci, and to have terminated fatally by means of the subsequent infection which they produced. Two are described as cases of primary infective periostitis, or, as it is known to us, of the acute periostitis and necrosis of young people; the third as one of endocarditis of parasitic origin—acute ulcerative endocarditis.

Quoting and adopting Lücke's words, the author remarks that of the disease which is known commonly as 'diffuse spontaneous osteomyelitis,' there is no comprehensive knowledge, and for it no universally accepted name.

Nearly all authors, however, agree so far that this is distinguished from other diseases of the bones by its malignancy and early assumption of typhoid characters; by its association with a pyæmic or rheumatic affection of the joints [and, as might have been added, by a particular distribution of metastatic abscesses in the viscera.—*Rep.*]; and by its appearance at first as a local affection, of which the outcome is often fatal; or if not, it leads to a separation of the epiphyses and to death of the bone.

The local process nearly always assumes the form of an osteomyelitis or periostitis, associated with severe pain and fever, and then comes a phlegmonous suppuration of the tissues enveloping the bone.

Resolution may occur, or necrosis, as just stated, with abscesses in various organs.

So striking is this secondary formation of abscesses, unassociated as it is with any wound, that some have held to the idea of an idiopathic pyæmia; but this view has not met with general acceptance. Since the recognition, moreover, of the rôle which micrococci play as agents for the production of the infective inflammatory products of pyæmia, Klebs and Von Recklinghausen, at the suggestion of Lücke, have attempted to solve the question whether micrococci are to be found in inflammatory foci with which at no time has there been any atmospheric contact—and they have proved the existence of such vegetable organisms both in the primary and secondary foci in two separate cases.

Upon the strength of these facts, Lücke argued that, inasmuch as cases of acute periostitis are marked by changes which in their course and pathological character have the most complete analogy with traumatic pyæmia, there is ample ground for assuming that they too, like it, result from infection.

The following cases give additional support to this hypothesis. [They are reported in the original at considerable length, but are abridged as much as possible here.—*Rep.*]

A factory workman aged twenty, of delicate constitution, though he had never been ill, had latterly had an excess of work, which had tired him very much. He was at work as usual on February 13, 1875, when he suddenly at 1 P.M. felt chilly and was obliged to take to his bed. The feeling of cold subsided towards evening, and he then noticed for the first time a rather extensive flush on the left instep. For this, he was unable to suggest a cause. He had considerable pain in that foot, and also from thence to the knee-joint. He chiefly suffered, however, from a feeling of fatigue and a general soreness whenever he was touched. He was now seen by a medical man, who found him with severe fever, loss of appetite, repeated vomiting, and disturbed sleep.

He lived in poor circumstances, the house in which he was being new and still damp. The general hygiene of the place was not good. He was brought to the hospital five days after the commencement of his illness, in a condition which rendered the formation of a correct diagnosis impossible. He was quite wanting in sense. He would put out his tongue when told, but could give no information either of his previous history or present state. Temperature over 105° Fahr. ; pulse 108 to 140. Respiration was laboured and very frequent, now and then clipped and irregular, as if it caused pain. The heart's action was very frequent, but there was no bruit nor perceptible rub, and no increase of the cardiac dullness. The chest was filled with râles (œdema of the lung) which precluded any reliable examination of the contained viscera. The splenic dullness was diminished rather than increased. The left lower extremity was swollen in its whole length ; some distended venous radicles were visible in the region of the left epigastric vein, but no thrombus could be felt. The left foot was swollen and intensely painful. Large doses of quinine were administered, but he died on February 18, the temperature falling slightly the last few days of his life. The diagnosis which appeared most probable was septicæmia with infarcts in the lungs, probably starting from some bone-affection.

Necropsy, fourteen hours after death.—There was no rigor mortis. Superficial extravasation of blood was found in the subcutaneous tissue of the dorsal surface of the left foot. A small quantity of pus was found beneath the periosteum of one of the tarsal bones and in one of the tarsal joints, the affected bone being deeply injected and its surface rough. The left thigh was much swollen, some of the muscles being œdematous. The periosteum throughout the whole shaft of the femur was infiltrated by pus, which in one spot had collected into a small abscess. Close to the periosteum of the lower third of the femur, which was rather swollen, but showed only a little purulent infiltration, was a small vein full of fluid pus running upwards some distance till it was finally lost in the loose periosteal tissue. The periosteum was separated from the surface of the bone by a large quantity of reddish pus, the membrane thus forming a sac round it. At only one spot on the posterior face was it still normally adherent. The bone was very pale, but here and there tinged, as if by imbibition of the colouring matter of the blood, slightly red. The lower fourth of the femur was covered by a cream-like yellow material

which had the appearance and consistence of marrow. The left knee contained clear synovia ; the cellular tissue around it being œdematous. In the muscles of the right thigh was one minute abscess. The extreme infiltration of the periosteal tissue with pus displayed itself in frequent long lines extending far into the deep muscles. The transverse section of the femur showed a pale cortex, and an œdematous state and violet injection of the medulla. The pale medullary parts were grey-yellow, and gradually lost themselves in the surrounding tissue. There were no abscesses. In the right profunda and one of the other veins of the thigh, clot was adherent to some of the valves. The intermuscular tissue of the right arm was œdematous. The anterior mediastinum was œdematous and injected. The pericardium contained some blood-tinged serum, and its two layers were plastered with shaggy membrane ; and miliary abscesses were scattered through the muscle of both ventricles. The endocardium was healthy. Both pleuræ were inflamed. Both lungs contained hæmorrhagic infarcts and patches of lobular pneumonia both in their substance and superficially, and delicate zig-zag outlines were seen in these organs which corresponded to lymphatics or blood-vessels full of pus. In the left lung was one abscess. The spleen was not large. The kidneys showed many dark red points superficially, which had the appearance of hæmorrhagic Malpighian corpuscles. The stomach contained many superficial follicular ulcers.

Summary.—Suppurative periostitis of the left femur with phlebitis of a periosteal vein ; abscesses in the neighbouring muscles, suppurative periostitis of one of the tarsal bones ; suppurative pericarditis and myocarditis ; suppurative pleuritis with hæmorrhagic infarcts ; and commencing abscesses in the lungs.

The microscopical examination of the blood showed a small number of isolated spheroids of the appearance of the diphtheritic micrococcus, but of which the nature could not certainly be ascertained, because they were too few to admit of the application of chemical reagents. But micrococci were present in extraordinary numbers in those parts of the pericardium and muscle which bordered upon the abscesses in the heart, and also in those recently inflamed spots which were covered by fibrin. The parasites were arranged partly as large columns, partly as a generally diffused infiltration of the implicated tissue. Within the abscesses of the cardiac muscle too, small balls of like organisms were found, though they required long search for their discovery, because of the quantity of pus-cells. That they were really parasitic, and not mere masses of detritus, was proved by their behaviour with acetic acid and potash. Their contour remained unaltered, though they became paler in colour. Similar formations were recognised on the pleura over the hæmorrhagic infarcts ; and the whitish lines in the crepitant and blood-gorged lung were found to be capillaries and small arteries, which were often freely plugged with embola of fat. Near and between the fat-plugs were small and large balls of micrococcus. Again, in the reddish-gray hepatisation and the partly softened hæmorrhagic infarcts, the presence of fungus and fat embola was proved without exception. The vessels were partially torn through, and micrococci and fat-plugs were seen enveloping each other both in the alveoli among the embryonic cells and blood, and in the lung-tissue.

The frequent occurrence of fat and micrococci in one and the same vessel points to some common source of origin for both kinds of embolon. For, on the supposition that they are derived from separate foci, even if it be granted that both might in their course along the blood-vessels be arrested in one particular vascular area, it is very improbable that both fat-embolon and micrococcus-embolon would in almost all instances be found in intimate association. Therefore the abscesses in the heart, or the suppuration between the femur and its periosteum, must either one or the other have been the source of both.

The former extended into the pericardial cavity, and it could therefore easily happen that, through the destruction of the subpericardial tissue by suppuration, which had been caused by micrococci, fat should be taken up with the micrococci and carried about by the blood-vessels or lymphatics. The derivation of embola from such a source is, however, the less plausible, seeing that the great quantity of fat displaced as embola bears no proportion to the small size of the heart-abscesses. And on the other hand a thick layer of medulla covered the denuded femur. This would find its way in the outer part of the periosteum, now converted by suppuration into a soft pulp, into one of the veins already charged with pus and micrococci; and this was obviously the main source for both fat and fungus embola.

The pus had denuded the femur of its periosteum over a large area, and at the same time provided it with an enveloping sac of great capacity. By this means the vascular communications between the medulla and periosteum were destroyed, and the continuity of the medulla of one part with that of another severed also. Free medullary fat could thus very easily find its way into any ruptured vessels; and this would be the more likely, because of the pressure exercised towards their open mouths by the œdematous swelling of the medulla. No micrococci were found in the medulla of the femur, neither could their existence be proved with certainty in the abscess about the left tarsus nor in the abdominal viscera.

But if the primary focus of disease, from which all the metastatic processes are to be traced, was femoral, then the occurrence of micrococci in the inflamed periosteal veins needs to be explained. We are not inclined to adopt the opinion that the development of fungus was second to a primary suppurative affection, because, though such a possibility cannot be combated, yet we frequently see just the opposite, viz. suppuration following in the train of the invasion of a part by fungus.

It is very probable, then, that micrococci were the cause of the periostitis; but, if so, how did they reach the periosteum? One can hardly admit that they come by accident, if they play an important part in the process. Moreover, not much is done towards the elucidation of the subject, if we determine the localisation of these parasites in the inner organs to be entirely dependent upon accident. And if we look over many cases in which the etiology is still obscure, we shall find that some weak spot is frequently present by which these parasites obtain a basis of operation against other parts—here a wound, there some inflammatory and softened state of a mucous surface, possibly even a mucous membrane which has suffered some small loss of epithelium. I therefore follow Lücke's explanation of the ostitis due to mycosis, and hold that, in consequence of

injury or catarrh, some local disturbance of the circulation occurs, and that from such places both deteriorated blood and micrococci become diffused through the body.

With regard to the course which the fungus took in this case, failing an open wound or any primary intestinal affection, and seeing that the pulmonary foci were manifestly secondary, I must have recourse to the hypothesis which seems very probable, that the organisms permeated the body with such rapidity from the lung or intestine, that the very rapidity of the process allowed no time for the development of the usual local changes. Perhaps the numerous recent catarrhal ulcerations of the stomach would point to infection by means of the gastric mucous surface.

Although no fungus-colonies could be demonstrated in this part after a careful search, yet one cannot but suspect that through some such door micrococci found their way, and that, favoured by some commencing circulatory disturbance, they developed into larger colonies in the periosteal vessels, whence in turn originated the embolic abscesses and the inflammatory changes of the lung and pleuræ.

In another case of suppurative periostitis of the humerus without the formation of visceral abscesses, the symptoms were so similar to those in the one just detailed, that I could not but consider it also as an example of infective periostitis. From the report, the following points may be recorded.

A smith, aged eighteen, of moderately strong build, was admitted to the hospital on December 17. He could just give his name and age, but could not tell of the previous course of his disease. He was flushed, and rather livid. He spoke very slowly, as if conversation were a trouble to him, and during the examination he sometimes laughed convulsively. His general appearance betokened meningitis, or typhus with pronounced nervous symptoms. The chest was normal, respiration laboured. He offered resistance to passive motion of the right arm, and appeared to suffer pain when it was drawn outwards, but the origin or exact seat of this could not be detected. The heart's action was very frequent, and its tone muffled. Splenic dulness was much increased. The temperature ranged from 104° Fahr. to 109° Fahr.

Resumé.—Very high continued fever; great splenic enlargement and meteorism. The most probable diagnosis was one of typhus, or ulcerative endocarditis.

At the necropsy, seven hours after death, the right lung was found to contain near its surface a soft round hæmorrhagic focus, with some œdema, grey hepatisation, and purulent bronchitis of the smaller tubes. The spleen was enlarged. The tonsils were rather swollen, so also was the mucous membrane of the base of the tongue. There was slight injection of the mucous membrane of the small intestine over a large area, and a little swelling of the follicles of the large intestine. The cellular tissue over the biceps of the right arm was very œdematous, and the hinder aspect of the upper half of the periosteum of the humerus thick, and separated from the bone, a small quantity of blood-tinged purulent serum lying between the two. The bone was rough. Near the head of the bone was a thin layer of granulation-tissue, somewhat intimately adherent to the bone, by sprouting from many open lacunæ. One of the veins coursing over the capsule of the joint was plugged with grey-white firm thrombus. The joint-capsule was free. The medulla was of clear red colour.

Anatomical Diagnosis.—Fungous periostitis of the humerus, with erosion of the bone; partial suppurative periostitis, and separation of the periosteum; thrombosis of a capsular vein; hyperæmia and œdema of the lung, with hæmorrhagic infarcts; lobular pneumonia, atelectasis, bronchitis.

The last case had, like those described by Lücke and others, the general character of typhus. It differed from them in the small amount of local disease of the bone and the absence of secondary abscesses. The process in the upper arm was obviously already undergoing repair, as shown by the soft granulation tissue under the periosteum. The lung-affection (atelectasis, hæmorrhagic infarcts, lobular pneumonia), was most probably caused partly by the severe bronchitis, partly by embola from the venous thrombosis in the neighbourhood of the right shoulder-joint. Micrococci, indeed, were nowhere to be found, either in the diseased bone or in the remaining viscera. But this is hardly to be wondered at, since the primary disease of the bones had for the most part passed away. The absence of the old and recent changes in the remaining organs, which are sometimes to be attributed to micrococci, will but little astonish us, since such secondary mycetic processes are not more constant than is a simple embolism after a primary thrombosis. It appears most probable that the fatal result in the last case was brought about by the lung-affection, which, to all appearance, had developed, at least partly, independently of the bone-disease.

Eberth concludes these two cases by saying that, though but a scanty contribution, he felt bound to publish it, since, excepting the observations of Lücke, Klebs, and von Recklinghausen, no further anatomical inquiries on the course of infective otitis and periostitis have been brought forward.

Fungous Endocarditis.—A servant-maid, aged twenty-five years, had suffered eight years before with articular rheumatism, for which at that time she had lain long in hospital. Since then she had never been thoroughly well. Her more special complaint was of swelling of the foot, which made its appearance after but moderate exertion, and even without it, towards evening; which was gradually increasing; and which caused much pain in walking. She had never noticed this before the rheumatism. She had also very frequent pains of wandering rheumatic character in the hands and feet. Moreover, very considerable sweating had commenced since she had been confined to the house. She complained of no palpitation, cough, stomach-affection, headache, or vertigo. In the week previous to her admission into hospital, she felt herself very unwell. The feet were swollen, and her general condition, besides the fixed local pain, had deteriorated. For this the patient gave the credit to long absence of the menses, and she had taken on that account several hot foot-baths.

On April 22, not long after a hearty dinner, which to her was unusual, and while engaged in raking up wood, with her body bent forwards, she suddenly fell to the ground. On attempting to rise, it was observed that she could not walk, and dragged herself to the bed. Those near her were positive that the patient was not at first deprived of consciousness. She opened her eyes, if spoken to, and understood apparently what was said to her. No fits or convulsions were observed. Whether the patient made any movement with the right arm or leg, was not noted outside the hospital, but she surprised those around her by holding the right hand fast in her left.

Later, violent vomiting set in, which continued till evening. Fluids, such as tea and milk, which were administered, were swallowed without difficulty, but directly vomited again. Towards evening the vomiting ceased, and she now lay with closed eyes and in deep insensibility, and so remained till her admission.

She then lay apathetic, but not completely insensible; no coma, properly speaking, was present. This condition lasted for thirty-six hours. She then began to arouse in some slight measure. There was no ptosis or strabismus; the right pupil was moderately contracted, it reacted better than the more widely dilated left. The dilatation of the latter pointed to an affection of the oculo-motor nerve and of its fibres which controlled the movements of the pupil. The lips were livid. The left angle of the mouth was somewhat lower than the right, but any considerable difference in the tone of the lips could not be proved.

The patient made some movements at times, but only with the left extremity. The right arm when raised fell back immediately. In the same manner the right knee when flexed sank back again at once. Moderately strong heart-movements were visible. The impulse in the fifth intercostal space in the nipple line was strongly perceptible. A very loud systolic sound was heard near the mitral valve, and the same was also audible in the aorta.

On April 25 the condition of the patient, so far as concerns the want of intelligence, was somewhat worse; at least, there were no signs of attention to be perceived, or of any attempt at reply to queries. The pupil of the left eye was wider than it was on the previous day, and immovable; that of the right eye was narrow and also without reaction. There were no convulsive movements; no rolling of the eyeballs; they remained quiet. In this state their axes diverged considerably; both eyes turned outwards, and the right did so more markedly than its fellow. This indicated some insufficiency of the internal recti. The eyes were kept shut; and since absolutely no spontaneous movement occurred, it was not possible to determine whether ptosis were present or not.

No retinal hæmorrhages could be seen on ophthalmoscopic examination. The blood-supply to the retina was moderate; the veins were overfull; the arteries nearly empty. The left optic papilla had an indistinct margin, but it was more distinct on its outer side. She had the *Stauungspapilla*. There was no venous pulse.

The patient was restless during the examination, and made reflex movements of resistance, but still only with the left arm and leg. With the right only a feeble movement of the hand could be perceived. The features became red and pale by turns. Pulse forty-four, quickened to fifty-two by excitement. The heart's impulse was forcible. The area of dullness was increased, and there was a loud rough prolonged bruit over the mitral valve. The second sound was indistinct. In the aorta was a shorter softer systolic bruit, and the second sound was somewhat lengthened. Over the tricuspid valve was a feeble systolic bruit; the second sound was good. Nothing striking was perceived in the veins of the neck. The patient swallowed badly. Reflex movements were almost lost; voluntary movements were failing.

The subsequent symptoms were involuntary evacuation of the excreta and then deep coma. She was completely feverless till April 26, when the tempera-

ture rose to 102°. She died on the 27th, with well-pronounced œdema of the lungs.

Diagnosis.—Embolism of the left middle cerebral artery; hæmorrhage compressing the left third nerve, and possibly also the two facials.

Necropsy, three hours after death.—The dura mater was injected. The arachnoid was dry; the left hemisphere was more voluminous than the right. In the right posterior frontal convolution was a lentil-sized stellate scar, of brown colour and situated superficially.

In the neighbourhood of the left carotid was a shrunken spot about a centimètre in diameter on the surface of the brain, which was covered by a layer of tenacious grey-red pus. The subarachnoid space was infiltrated with pus at the same spot and to a similar extent. Flaky reddish-grey pus crossed the left optic tract and nerve and the third nerve. The latter was wasted and gelatinous-looking. The left carotid artery for a centimètre in length, at its exit from the carotid canal, was completely plugged by fine decolorised clot. The commencement of the corresponding middle cerebral artery contained pus, the wall of the vessel being whitish-yellow and charged with pus. A small collection of pus was found on the surface of the left hemisphere.

The left lateral ventricle was dilated, and the hemisphere including the central parts was extensively softened into a white pulpy material.

In the pericardium was a moderate quantity of rather blood-tinged serum. The heart was enlarged. The left ventricle was strongly contracted. On the hinder face of the visceral layer were small punctiform ecchymoses. In the right and left auricles were much fluid blood and soft clot. The tricuspid and pulmonary valves were free; the mitral was much contracted and thickened, and a very delicate granular deposit fringed the line of closure of the valve, and also the rather dull endocardium of the left auricle here and there. On the free edge of one of the flaps of the mitral valve, were two old polypoid fibrin-clots as large as hemp-seeds. Besides these, the tendinous cords of the retracted mitral were for the most part thickened and changed into cylindrical strings. Two of the tendons floated free and had swollen ends covered with clots. The endocardium of the left ventricle was thickened and dull. The left ventricle was greatly hypertrophied, of speckled appearance, and had numerous studded deposits of connective tissue throughout the whole thickness of its muscle wall.

The lower lobe of the left lung contained grey-red patches of soft lobular hepatisation, varying in size from a pea to a cherry. The smaller bronchial tubes on the right side were plugged by pus, and the lung-tissue corresponding was collapsed and in a state of grey-red hepatisation.

The spleen was normal in size, but distorted from adhesions to the diaphragm. The surface corresponding to these was puckered. The serous surface was thickened. The substance was firm. The Malpighian corpuscles were distinct but scarce. Both kidneys were somewhat scarred, and contained numerous miliary abscesses in the cortex and pyramids.

Anatomical Diagnosis.—Old endocarditis and thickening of the mitral valve with recent fibrinous, and probably micrococcous deposit. Old and recent endocarditis. Thickening of the chordæ tendinæ. Hypertrophy of the left ventricle, with chronic myocarditis. Embolism of the left intracranial carotid;

circumscribed suppurative meningitis in the neighbourhood of the plugged artery; softening of the brain. Purulent bronchitis; atelectasis and lobular pneumonia. Wasting of the kidneys. Hæmorrhages into the kidney and commencing abscesses.

From the result of the necropsy, it could hardly be that in this instance the embolism of the intracranial carotid was occasioned by a bland plug. For not only was the wall of the artery in the region of the embolism infiltrated by pus, but the suppuration had extended to the neighbouring optic and third nerves.

In the case of embolism occasioned by *indifferent* fibrin-plugs, no such remarkable suppurative arteritis or periarteritis is evident; their presence therefore suggests that the clot on the mitral and endocardium of the auricle, whence the carotid embolon obviously came, was not simply a portion of detached clot, but in addition to this possessed some irritant (inflammation-exciting) property to which each suppurating spot owed its existence. The microscopical examination, which was undertaken three hours after death, showed that the soft granular deposit on the endocardium of the auricle was due in great measure to large and small micrococcus-colonies and to very delicate fibrinous deposits; while, on the other hand, in the larger valve-clots the fibrin preponderated, while the micrococci only lay upon the surface. The endocardium of the left auricle was also, at least superficially in the region of the fibrin-deposit, thickly studded with micrococci. The clot upon the mitral valve was composed of moderately fresh fibrin superficially, though of older date in its substance. Here and there it was covered with micrococci. In some places, the well-known finely granular softening was present. In one spot, micrococci lined clefts and fissures which stretched from the surface to the centre of the clot.

When treated with an alkali, the parasites underwent no change, though the softened finely granular fibrin lost its colour, and finally disappeared.

The mitral and the auricular endocardium were moderately thickened, the surface for the most part smooth.

The wall of the carotid in the region of the embolon showed a large collection of pus-corpuscles. The naked eye had previously detected this infiltration of pus. The section of the artery which was made immediately after the removal of the brain from the alcohol in which it had been hardened, showed an old firm fibrin-plug whose outer layer was richly studded with micrococci, and whose surface was enveloped in a thick coating of similar organisms.

As has been shown in the report, there existed an old endocarditis with fibrinous coagula and an entirely new and obviously primary mycosis of the valve.

[The value of reports of cases such as these can hardly be over-estimated at the present time, when some attempt is being made to assign to organisms like micrococci their proper place in the rôle of pathological processes. It is indeed at first sight almost a reproach to us that, since the diseases which these reports portray are by no means uncommon, the questions raised by them, not now for the first time, have not ere this been settled. But in justice to many it must be said that the want of recorded cases is probably due, not to the paucity of observations, but to the fact that observers hardly as yet feel satisfied in forming an opinion whether micrococci are the cause or the effect of infective in-

inflammations. Eberth appears to have decided in favour of the potency of micrococci as originators of inflammatory changes; but the arguments he uses are by no means comprehensive enough to carry anything like conviction to a wavering mind. To take for instance the case of ulcerative endocarditis; it is quite true that the vegetations on the valves of the heart in that disease may be crowded with micrococci; that they are so, the reporter has verified in several instances. But he is equally convinced that the blood of such patients does not usually contain anything of the same nature, and the latter observation is surely irreconcilable with the supposition that the diseased valves are spreading these hurtful bodies in all directions. He has also examined, as part of the larger question of the relationship between bacteria and pyæmic processes generally, the blood of several cases of acute periostitis, and in those also nothing like micrococcus could be detected. The appearance of the blood in the two cases—ulcerative endocarditis and acute periostitis—is very different; in the latter it is normal, or nearly so; in the former, on the other hand, it is quite characteristic of the disease, for the blood is usually crowded with minute motionless particles. But that these are not micrococci, is evident by their want of resistance to chemical reagents; and they are most probably formed of degenerating fibrin whipped from the diseased surfaces. —*Rep.*]

J. F. GOODHART, M.D.

ANATOMY AND PHYSIOLOGY.

STIRLING ON THE CUTIS OF THE DOG.—The *Reports of the Royal Saxon Academy of Sciences* for 1875 contain a contribution to the anatomy of the cutis of the dog, by Dr. W. Stirling.

1. *Methods.*—The skin to be examined was stretched over a glass ring and digested in artificial gastric juice, prepared by adding 0.2 per cent. of hydrochloric acid to carefully prepared glycerine-pepsine. The temperature was maintained at 38° to 40° Cent. (100.4° to 104° Fahr.) The fluid was renewed every two hours and digestion was generally sufficiently advanced in four to six hours. The skin, still on the ring, was then washed with water, and placed in distilled water for twenty-four hours. During that time it had swelled to four to six times its thickness, and was in a suitable condition for making sections which could be examined at once or after being stained.

The leg was injected with a clear watery solution of Berlin blue from the femoral artery, with a pressure of 100 to 200 millimètres of mercury, a cord being screwed tightly round the limb above the point of injection. The solution was allowed to flow into the vessel as long as it would go—usually for a period of many hours. By this process the vessels were filled with the blue, whilst the water passed into the tissues and produced oedema.

2. *Results.*—In the dog the bundles of fibrillary tissue are mostly parallel to the surface of the cutis, and are held in their position by the elastic fibres which interlace amongst them.

There are two kinds of cells in the stroma of the cutis. The nuclei of the one kind are spindle-shaped, of the other round. The cells with round nuclei are mostly found near the vessels, that is, in the superficial part of the cutis and in the subcutaneous tissue.

It is suggested from their position that they are lymphatic cells.

When digestion is far advanced, part of the *Zell-platte* which belongs to the cell with spindle nuclei, and which the author considers to be analogous to the *Zell-platte* of Schweigger-Seidel, is sometimes preserved. When digestion is not so far advanced, and the arrangement of the fibrillary bundles is undisturbed, it can be seen that the long axis of the spindle nucleus is parallel to the direction of the bundles, and that the spindles lie between the bundles. It is inferred that the clefts between the bundles form spaces which are filled with lymph-fluid.

As in the human skin, whilst the hair-follicles, fat-lobules, and sebaceous glands have each a separate blood-supply from a small artery, the connective tissue between the fat, muscles, and glands, is destitute of capillaries.

The sweat-ducts (the popular idea that in dogs there are no sweat-glands is a mistake) open into the hair-follicle above the sebaceous gland, but at some distance from the epidermis. The sweat-gland is composed of a layer of flat cells, a structureless membrane on which these lie, and then the cells of the gland. A similar layer of flat cells has been described in man by Heynold, but he says that they are followed immediately by the gland-cells.

The erector pili is composed of elastic fibres, which spring from a network which surrounds the hair-bulb, and which pass in a tract to the surface of the cutis, where they spread out and join the other fibres of the part. Between and amongst these elastic fibres, the smooth muscle-cells are insinuated.

After prolonged digestion the bundles of fibrillary tissue undergo a change by which they present an appearance like that usually presented by muscular fibres. This is due to the gelatinous substance being dissolved, a sheath remaining, which, being thrown into transverse folds, simulates the transverse markings of muscle. Both the larger and the very fine bundles have such sheaths.

When digestion is continued until the skin is reduced to a pulpy mass, what remains of the capillary blood-vessels is a very delicate structure composed of rows of spindle-shaped cells.

[Biesiadecki (Stricker's *Handbook*) describes in the human skin spindle-shaped cells and also round or oval cells similar in size and form to colourless blood-corpuses. The admirable plates which accompany Dr. Stirling's paper enable the reader to form an independent opinion regarding the cells which he describes. The spindle cells figured resemble similar elements lately described by the reporter as existing in the cornea, and their arrangement as regards the fundamental substance is the same in both instances. The remains of the *Platte* described in Dr. Stirling's text as being sometimes adherent to the cell is nowhere shown in the drawings, and the analogy with the *Platten* of Schweigger-Seidel in the cornea or the cells described by Ranvier in tendon, instead of being supported by them, seems to the reporter to be contraindicated. Schweigger-Seidel's description of his *Zell-platten*, and Ranvier's of his tendon-cells, can hardly be made to coincide with the fine anastomosing spindle elements figured by Dr. Stirling.

If the other cellular elements figured be nuclei, which, from the appearance represented, seems probable, then nothing is shown of the cells to which they belong; but, from the form and size of the nuclei, the reporter infers that they belong to flat

cells, and to these latter the analogy with the *Platten* of Schweigger-Seidel would, he believes, be more applicable. If they be not nuclei, then they can only be lymph-cells; but this does not coincide with the description in the text, which states that the cells have round nuclei. Only one round substance is figured for each element.

The isolation of the sheaths of the bundles is one of the most important results obtained by Dr. Stirling's method. The existence of a sheath investing the bundles of connective tissue has been maintained by several histologists on various grounds, but no evidence of it so complete as that given by Dr. Stirling has been hitherto found.—*Rep.*

G. THIN, M.D.

GUTTMANN ON THE IMPULSE OF THE HEART.—In Virchow's *Archiv*, Band lxx. p. 537, appears a paper on this subject by Dr. Paul Guttman, of Berlin, who entered into the discussion in consequence of recent articles by Marey, Wilckens, and Jahn. The first of these follows Arnold, Kiwisch, and Ludwig in explaining the cardiac impulse by the systolic hardening of the muscular walls. Wilckens attributes it, as did also Kornitzer in 1858, to a movement of rotation from left to right; while Jahn considers that the recoil of the heart, as well as its rotation, is concerned in the production of the impulse. The recoil theory of Gutbrod and Skoda explains the beat of the heart by the fact that the pressure, which during diastole is exerted equally on the walls of the ventricle, at the moment of systole becomes less at the arterial orifice than at the apex of the heart opposite. The heart is consequently driven away from the arteries with a force proportional to the velocity and quantity of the outflowing blood. The objections to this theory, that the ventricular walls, on which the balance of pressure would fall, themselves by their contraction produce a pressure to oppose it, and that the heart's apex is not opposite in a direct line to the arterial orifice, have been met by Skoda and others. The earlier experiments, by which it was attempted to ascertain either by ligature of the great veins, or by compression of the main arteries, what would be the result on the heart's action of preventing the systolic discharge from the arterial orifices, were not conclusive, because the pulmonary veins were left untouched. This omission was supplied in an experiment by Jahn, who ligatured the *venæ cavæ* and *pulmonales*, and in one by Guttman, who tied the arteries in one ligature, and all the veins in another. Both experimenters saw the downward movement of the heart cease the moment the ligatures were tightened. But these results may be also claimed as supporting a theory, suggested by Bamberger, that the locomotion of the organ in a downward direction is due to the elongation of the great arteries by the blood discharged into them, as well as Kornitzer's extension of this view, according to which the elongation of the vessels causes not only descent, but, in consequence of their spiral course, rotation also. On the other hand, the arguments for the latter explanation, founded on the pathological conditions of the organ, are not conclusive. The greater elongation of the great vessels, which must result from the more forcible injection of blood by a hypertrophied heart, would affect only the apex, and would not lead to the extended impulse observed; further, the occasional absence of an apex-beat in cases of considerable stenosis of the aorta, is no better explained on Kor-

nitzer's theory by the retardation of the flow into the aorta, and the necessarily slighter elongation of that vessel, than it is on the theory of Gutbrod and Skoda, by the slight difference between the pressures at the two extremities of the heart, when the usually rapid fall at the aortic orifice is prevented by stenosis. Finally, Guttman is of opinion that *no one* of the different theories explains *all* the phenomena, and that a satisfactory explanation of all the pathological conditions of the impulse of the heart will only be arrived at, when both the 'recoil' and the 'increase in size of the contracting heart' are regarded as equally well established co-operating causes. The recoil in the systolic movement of the heart downwards and forwards explains the apex-beat; the systolic hardening of the muscles of the heart-walls and the increase in its antero-posterior diameter explain the impulse of the base. That the latter is not usually observed under normal conditions, but only the beat of the apex, depends on the fact that the apex lies immediately against the wall of the chest, while the base is covered by lung, which hinders the conduction of its impulse to the surface. This conduction is further opposed by the backward movement of the base during systole, by the resistance of the ribs, as well as by the considerable thickness of the chest-wall (pectoral muscle and adipose tissue) at the points corresponding to the position of the base. Where these unfavourable conditions are not present, *e.g.*, in children with thin and yielding thorax, and in all cases where the heart lies in contact with a larger surface of the chest in consequence of retraction of the edge of the left lung (in phthisis of the left side), as well as in hypertrophy of the heart, then an impulse is perceived at the base as well as at the apex—the heart beats over a greater extent.

JACOBSON ON THE DISTRIBUTION OF HEAT IN THE COURSE OF FEBRILE DISEASES.—Dr. Louis Jacobson, of Berlin, gives the result of his observations in a paper published in Virchow's *Archiv für Pathol. Anat.*, Bd. lxx., Heft. 4.

The researches were undertaken with the object of testing the truth of Hankel's proposition, that 'the difference between the temperature of the axilla and of the surface of the body in the same individual is less in the febrile condition with increased temperature, than in the non-febrile state.' Hankel had recourse to thermo-electricity for the more accurate determination of the surface-temperature, making use of iron and German silver wires, soldered together and twisted into coils, which were laid upon the skin and protected from exposure by cupping-glasses. His observations were made on a case of gonorrhœal synovitis of the knee, on one of mild bronchitis with coryza, on one of tertian ague, and one of slight pneumonia. The surface-temperature differed least from that of the axilla in the cold stage of ague, and once indeed was nearly the same. Jacobson has made some modifications in the construction of the instrument employed. His elements consist of German silver and steel wires, soldered together, and pointed so as to form needles, which can be easily inserted beyond the soldered portions into the most superficial layers of the cutis. He gives tables of observations on ten cases, including rheumatic pericarditis and pleurisy, typhoid fever, pneumonia, articular rheumatism, and tertian ague. The temperature of the axilla was compared once or twice daily with that of the skin, in three or more of the following situations:—the chest, the abdomen

(right hypochondrium), the ball of the thumb, the thigh and the upper arm. A glance at the tables shows how changeable the distribution of the temperature is, both in febrile and in non-febrile conditions, while the constant difference, which Hankel found, is not recognisable in them. Sometimes the difference in heat between the axilla and the superficial layers of the cutis is less in pyrexia than in apyrexia, sometimes greater; and the variations at different points of the surface in the same individual occur quite irregularly. Further, while the temperature is stationary in the axilla, the surface-heat oscillates considerably, but it has an almost constantly higher position during the course of fever than during convalescence. The observation on tertian ague shows, in opposition to Hankel's experience, that, during and immediately after the rigor, the difference between the internal and peripheral temperatures was by no means less than during the previous apyrexia. Jacobson concludes with the remark that his observations are in favour of the view that, even at the height of fever, the cutaneous vessels alternately contract and dilate, and that hyperæmia and radiation of heat from the surface of the body may vary within wide limits, not only at different times, but also in different parts at the same time. The results are reconcilable neither with the hypothesis of a paralysis, nor with that of a tonic spasm of the muscular coats of the cutaneous vessels.

MEDICINE.

MODEL ON THE EXCISION AND COMPOSITION OF A WANDERING GALL-STONE.—Dr. A. Model, of Nördlingen, records the following case in no. 41 of the Munich *Aerztliches Intelligenzblatt* (October 12, 1875). A publican's wife, aged fifty-five, had suffered for about one and a half years from occasional pains in the abdomen, slight and unfrequent at first, afterwards becoming more frequent, and gradually very severe and colicky. For the last six months the pains were strong enough to bend her double; and for a month she had kept her bed entirely. About an inch and a half to the right side and below the navel there was a minute sinus, just admitting a darning-needle, from which a very little thick, pale, yellowish fluid could be squeezed out. This was near the centre of a red and slightly swollen patch in the right hypochondrium, about the size of a small saucer. A fine probe, introduced

with some difficulty, in the outward direction, reached, at a depth of about three-quarters of an inch, a rough, hard body, which sounded, when struck, like bone, or a moderate-sized pebble. Further soundings gave the impression that it was rough, gritty, and not very hard. The patient being timid, it was removed under the colourable pretext of exploring, by dilating the sinus with a scalpel, and seizing the stone—for so it proved—with Bruns's sequester-forceps. In form and bigness it resembled a nutmeg. It was covered with a very dark crust, with a thickness of two to three millimètres (equal one-eighth of an inch nearly), and this, the softest part, was rough, crumbly, and porous. Within this a glittering mass, rich in cholesterin, appeared. The stone was perfectly encysted in the abdominal wall, and the lining or wall of the cyst was extremely smooth. No deeper opening towards the gall-bladder or liver was discoverable. The gall-stone was sawn in two, and showed in its interior a sort of marbling not unlike a nutmeg, only there were more radiating lines. With a lens, numerous glittering particles were easily seen. It had a sort of greasy feel, but no proper nucleus was discoverable. Drs. Rölhe and Frickhinger gave the following analysis for 100 parts: Cholestearine, 46.047; margarin, 1.161; alcoholic extractives (?), cholic and choldidic acid, and dyslysin (?), 3.194; bile-pigment and mucus, 21.297; inspissated bile, 2.904; carbonate of calcium, 16.650; phosphoric acid and magnesia, traces; water, 6.582; loss, 1.165 = 100. The patient made an excellent recovery; she was allowed to get up in ten days, and the sinus healed entirely in five weeks. The only treatment was a compress of charpie, with a bandage, great cleanliness, and occasional applications of nitrate of silver.

TUTSCHEK AND ZAGGL ON PARACENTESIS THORACIS BY MEANS OF THE PNEUMATIC ASPIRATOR.—In nos. 40, 41, and 42 of the Munich *Aerztliches Intelligenzblatt* (October 5, 12, and 19, 1875), Dr. Tutschek, surgeon-major in the royal household, and Dr. Zaggl, of Niederviehbach, communicated the results of their late experience in the treatment of pleuritic effusion and empyema. The cases of the former are partly from hospital, and partly from private practice, and are a continuation of a paper by him in the same journal (no. 2, for 1874). Those of the latter are from private practice, and are given at some length. For convenience of reference, both sets are included in the subjoined table; although in the original only Dr. Tutschek's cases are tabulated.

The remarks appended to these cases show that many of them presented symptoms of great severity. The results are encouraging; the more so, as some appear to have been operated upon in crowded wards. The operation of aspiration is evidently growing into favour in Germany, since one instrument-maker is stated in this article to have sold seventy aspirators very lately. Cases by other operators are mentioned; but the details are not given. [The experience of Drs. Sansom, Cayley, and the reporter at the North-Eastern Children's Hospital has shown that very great relief is sometimes afforded by the withdrawal of only a few drachms of fluid. In fact, as Herr Zaggl puts it, the operation is a first-rate diuretic. The translator regrets that, either from Gallophobia or some other cause, no mention is made of Dr. Dieulafoy; and the operations and instruments are spoken of as if purely German!—*Rep.*]

TABULAR STATEMENT OF TWENTY-SIX CASES OF PARACENTESIS THORACIS BY MEANS OF THE PNEUMATIC ASPIRATOR, IN CASES OF SEROUS EFFUSION INTO THE PLEURAL CAVITY.

Number of case for reference.	Sex.	Age.	Side affected.	Duration in days of effusion before first puncture.	Number of operations.	Quantity of fluid removed in ounces.	Colour, etc., of the fluid.	Percentage of solid constituents in dried condition.	Result.	Period, in days, till cure or death.	Remarks.
1	M.	21	Left	15	4	{ I. 14 II. 49 III. 27 IV. 26 I. 68 II. 1½ III. 5 }	Yellowish	{ I. 10'0 II. 12'8 III. 12'0 IV. 6 I. 10 II. ? III. 4'3 }	Died	117	{ Cheesy masses in lungs. Tubercular ulcers in the bowels.
2	M.	21	Right	32	3	{ I. 14 II. 49 III. 27 IV. 26 I. 68 II. 1½ III. 5 }	Greenish Yellow	{ I. 10 II. ? III. 4'3 }	Died	57	{ Effusion became purulent. Endocarditis.
3	M.	23	Left	32	1	38	Yellowish	12	Cured	28	—
4	M.	23	Right	39	1	37	Pale yellow	6	Cured	21	—
5	M.	22	Right	13	1	38	Greenish	5	Cured	44	Intercurrent gastric disease.
6	M.	22	Left	38	1	35	Sanguineous	3'7	Cured	39	Slow convalescence.
7	M.	21	Right	24	1	80	Yellowish	8'3	Cured	10	—
8	M.	29	Left	18	1	62	Yellowish	7'3	Cured	10	—
9	M.	25	Right	27	1	64	Yellowish green	5'6	Cured	10	—
10	M.	12	Right	39	1	4½	Yellowish	6'9	Cured	19	Dr. Ranke operated.
11	M.	22	Left	25	1	35	Greenish yellow	6'6	Cured	7	—
12	M.	21	Left	31	1	34	Yellowish	6'6	Cured	18	—
13	M.	22	Right	31	1	30	Yellowish	7'7	Cured	11	—
14	M.	32	Right	15	2	{ I. about 33 II. about 30 }	Greenish yellow	?	Died	70	{ The effusion was cured. He had tubercular pleurisy of left side, and milary tubercles in peritoneum.
15	M.	20	Right	7	1	15	Yellowish	12'5	Cured	20	—
16	M.	17	Right	7	3	{ I. 30 II. and III. same quantity of pus. }	I. Yellowish	8'4	Died	106	—
17	M.	64	Right	26	1	33	Yellowish green	6'2	Died	61	—
18	M.	57	Right	38	1	28	Pale yellow	7'9	Cured	28	—
19	M.	53	Right	15	1	49	Yellowish	8'3	Died	22	Became purulent.
20	M.	24	Right	35	1	29	Much blood in it	8'8	Cured	38	Tedious convalescence.
21	M.	27	Right	22	1	82	Greenish yellow	7'3	Cured	8	—
22	F.	32	Left	about 70	1	A wine bottle.	?	?	Relief	—	{ Died 8 months afterwards of phthisis.
23	M.	21	Left	14 ?	1	21	{ Pale and very } albuminous	?	Cured	30	No relapse.
24	F.	48	Right	28	1	50	Very albuminous	?	Cured	28	—
25	M.	21	Left	4 or 5 months	1	{ Only exploratory : a few drops of pus. }	—	?	Died. Seeremarks	90	{ Operation with knife and drainage-tube. Great relief; but marastic symptoms set in, and he died of apoplexy (?).
26	M.	24	Left	6 days	2	{ I. 3 beer glasses of bloody serum. II. A great quantity of pus. }	—	?	Cured	—	{ Complicated with subcutaneous emphysema and pneumothorax.

W. BATHURST WOODMAN.

GUYOT ON CHOREA CURED BY ENEMATA OF CHLORAL.—Messrs. Goeltz and Auger (in *Gazette Hebdomadaire*, December 10, 1875, no. 50) relate the particulars of a very interesting case occurring in the service of Dr. Guyot, at the Lariboisière Hospital, Paris. The patient, a young woman aged twenty-two, was taken suddenly, on November 1, 1874, with general trembling, predominating on the left side, palpitation of the heart, constant pronation and supination of the left forearm, as many as sixty times in a minute, throwing forward of the leg, spasmodic contractions of the face, and other well-marked symptoms of chorea. She had already been submitted to various kinds of treatment—bromide of potassium for a fortnight, without any amelioration; tartar emetic, sulphur baths, quinine wine, bromide of camphor, opium, chloral (thirty grains twice daily), arseniate of soda, syrup of strychnia, ether-spray to the spine every second day, injections of eserine (which produced some slight amelioration), cold douche, dry cupping to the nape of the neck, valerianate of atropine, tartrate of iron, baths prolonged for two hours daily—but all without more than tem-

porary or very slight amelioration of the symptoms. The catamenia, which commenced at the age of fifteen years, had been regular; and once during the flow the movements ceased, but returned again immediately afterwards. She was sent to the country to recruit her health, and treatment discontinued for a time.

On May 18 treatment was recommenced. Hypodermic injections of chloral and morphia were given night and morning, as well as thirty grain doses of chloral twice daily. The morphia was gradually increased to eight centigrammes. Some improvement took place, the patient sleeping quietly by day as well as night without sickness or contraction of the pupils ensuing; but on waking, the movements reappeared.

At the end of a fortnight the movements had notably diminished; but a new symptom now appeared, viz., convulsive movements of the muscles of the larynx and the diaphragm, causing hiccough some fifteen times in a minute. These continued until July 9, when they ceased suddenly.

Choreic symptoms returned on the 22nd, in conse-

quence of emotion from the death of one of her parents. The morphia was gradually increased to sixteen centigrammes, injected thrice daily. Syrup of chloral, thirty-eight grains twice daily, was also given, but omitted as it destroyed her appetite. The morphia was increased to twenty centigrammes up to the 30th, when it was given up. On the 31st, the patient being more and more agitated, an enema of forty-five grains of chloral was administered.

August 1.—Two enemata of chloral were given; the appetite and digestion were excellent. Chloral in drachm doses, twice daily, was injected *per rectum*, and continued until the 15th, when the movements had completely disappeared, and the patient could write and sew. On the 28th the cure appeared complete, and on December 1 still remained so.

ARTHUR W. EDIS, M.D.

GIBNEY ON OSSIFICATION OF THE DORSAL MUSCLES.—At the meeting of the New York Pathological Society on October 13, Dr. E. P. Gibney (*Medical and Surgical Reporter*, November 20) brought before the society a girl, aged ten, who was the subject of ossification of the latissimus dorsi, scaleni, and erector spinæ muscles. Some months previously she had suffered from diphtheria, which left paresis of the vocal cords for some time afterward. In the early part of last spring she noticed a difficulty in bending her body forward. She was brought to see Dr. Gibney, by her mother, on September 14, for right scoliosis.

Dr. Janeway said that the case was a rare one, and the first he had ever seen; the disease was progressive in character.

Dr. Knapp stated that he had seen a case of the kind in Heidelberg, in a woman aged thirty, where most of the muscles were involved, and that the disease was still progressing.

Dr. Janeway thought that it would be advisable to divide the tendon of the latissimus dorsi, in order to free the arm. Dr. Heitzmann suggested the internal use of small doses of lactic acid.

SURGERY.

DENNIS ON THE TREATMENT OF AMPUTATIONS BY THE OPEN METHOD.—In a paper in the *New York Medical Journal* for January, Dr. F. S. Dennis, of the Bellevue Hospital, says that for over a year nearly all the amputations in Bellevue Hospital, in the third surgical division, have been treated by the open method, and the results have been surprisingly successful for hospital practice. This method of dressing amputations was inaugurated in Bellevue Hospital by Dr. James R. Wood, visiting surgeon. In fourteen consecutive major amputations, performed during Dr. Wood's service within the past year, there has not been a death, although his patients have all occupied the same wards that were vacated a year ago on account of puerperal fever. In addition to these amputations, there have been in these same wards other capital operations, including resections of the knee and elbow joints, and several amputations of the female breast, all of which have done equally as well as the limb-amputations.

In one case of subperiosteal resection of the elbow-joint, treated openly from the beginning, and in which there was no sloughing, erysipelas, or pyæmia, the temperature only on three occasions rose above 100 $\frac{3}{4}$ ° Fahr. In another resection of the knee-joint, only once did the temperature rise to 103° Fahr. In three amputations of the female breast, treated in these same wards, the temperature in each case was below 102° Fahr.

The cardinal principle involved in this method of dressing is that of preventing suppurative fever; and it is held that this object is best attained by leaving the stump entirely open, thus allowing free and continual drainage. After a limb has been amputated, the flaps are left entirely open. A pillow of oakum is placed under the stump, which is allowed to rest upon this support until the wound is nearly healed. A small piece of gauze is placed over the contour of the stump, and a cradle is placed over the limb, so that the clothes may not come into contact with it. No sutures are used except in the lateral skin-flap method. No adhesive plaster is employed, no oiled skin is placed over the stump, no bandage is applied, no dry charpie is stuffed into the wound, no fenestrated compresses are placed between the flaps; in other words, the stump is left entirely alone. The wound is allowed to drain freely, and the stump is gently washed at frequent intervals by means of an Esmarch's wound-douche. The water in this irrigator is impregnated with crystals of carbolic acid; and, after this ablution, balsam of Peru (which makes a fine stimulating application) is poured over

the granulating surface. The discharge which falls from the wound is removed every few hours in order to secure perfect cleanliness; and it is worthy of observation that this discharge will not decompose when exposed to the open air, but that it requires a warm temperature, such as exists in the stump itself, in order to develop putrefaction. The pus, thus coming away from a nidus of putrefaction which would otherwise be formed, falls upon a piece of sheet-lint, where the temperature is cooler, and thus does no harm. The stump is washed at frequent intervals until suppuration has nearly subsided in the wound, and then the flaps are gradually approximated by means of strips of adhesive plaster. Too much importance cannot be attached to the method of operating by the lateral skin-flaps. It affords the best facility for free drainage, and makes the most serviceable stump. It is important to dissect the flaps very long when they are subjected to the open treatment, as shrinkage often follows exposure to atmospheric influences. This lateral-flap method of amputating Dr. Wood has employed for many years with uniform success. Esmarch's elastic bandage has been employed in every case, and in no instance has sloughing, or any other complication, occurred. The stump after a week is capable of being moulded into any shape. During the entire healing of the wound, the greatest possible care is exercised in reference to the use of the instruments necessary to perform the dressing of the stump. No sponges are used in the wards. Each patient has his own bottle of balsam of Peru, and every instrument used in the dressing of one stump is thoroughly washed in carbolic-acid water before it is employed in the dressing of another. So far as has been practicable, a different set of scissors, dressing-forceps, and other instruments employed in the manipulation of a dressing, has been used, so that each patient had his own instruments, and in this way absolute cleanliness is secured. Each dresser invariably washes his hands in carbolic-acid-water after dressing one case before undertaking another, and any one who is dressing unhealthy wounds in the pavilion, or making necropsies, is not allowed to even assist in the daily dressing of healthy wounds. The advantages that are alleged to be possessed by this method of treatment of stumps are the following.

1. Suppurative fever is very much modified; indeed, it is almost obviated.
2. This method prevents all possibility of the formation of abscesses in the vicinity of the stump, which are apt to form in closed stumps even when they are most carefully watched.
3. Another great advantage is the absence of erysipelas in the wound, or in the cellular tissue in the vicinity of the stump.

MACEWEN ON WOUNDS IN RELATION TO THE INSTRUMENTS WHICH PRODUCE THEM.—In the *Glasgow Medical Journal* for January Dr. William MacEwen contributes a paper on the characters of wounds made with various blunt and sharp instruments. His remarks are founded on the observation, mostly at the Glasgow Central Police Station, of seventy-one cases, presenting one hundred and four wounds. He sums up his paper in the following conclusions.

1. Blunt instruments sometimes produce scalp-wounds having straight outlines and sharp clean

edges, which in these respects could not be distinguished from wounds produced by sharp-cutting instruments. 2. Scalp-wounds, which exhibit entire hair-bulbs projecting from the surface of their sections, have been produced by a blunt instrument. 3. Wounds exhibiting nerve-filaments or minute blood-vessels bridging the interspace between the lips of the wound, toward the middle of the depth of the section, while the tissues have receded all round them, below as well as above, have been produced by blunt non-penetrating instruments. 4. When a wound, even with sharp well-defined margins, bears in contour a resemblance to an osseous ridge in close proximity, there is a *probability* that it was produced by a blunt instrument through forcible impact against the underlying osseous ridge. 5. Cut hairs found in the immediate vicinity of a wound are valuable aids in determining whether a sharp or a blunt instrument has been made use of. 6. As to the diagnosis between wounds produced by instruments of the knife kind and other sharp-edged substances, such as glass, earthenware, etc., no dependence can be placed on the mere regularity of outline or sharpness of edge, or the reverse. 7. Sharp clearly defined wounds in certain cases present peculiarities in their terminations which may be sufficient to enable a probable diagnosis as to whether they were produced by a knife or a portion of glass or earthenware. 8. The same instrument, used by the same person in delivering several successive blows, may produce wounds of different character.

BIGELOW ON THE TREATMENT OF ERECTILE TUMOURS BY CENTRAL CAUTERISATION WITH NITRATE OF SILVER.—In the *Boston Medical and Surgical Journal* for January 6, Dr. Henry J. Bigelow describes two cases in which erectile tumours of a formidable nature were easily obliterated by the injection, with a subcutaneous syringe, of a few drops of a solution (equal parts by weight) of nitrate of silver in water. If the tissues be firmly compressed about the orifice of the tube, after its introduction, an eschar of the solid tissues is produced, soon enveloped by coagulum adherent from inflammation, with general blood-stasis in the neighbourhood. While the eschar thus made is more distinct and firm than that of acid or of the perchloride of iron, the expression of the blood probably diminishes the danger of embolism. The ultimate result is abscess and solid cicatrization. The first of the cases was one of a large and pendulous under lip, which was so solidified by a number of simultaneous injections that a V-shaped portion was finally removed from it. The second was one of cirroid aneurism in the cavity of the orbit, which could not have been treated effectually by ligature without sacrificing the eye.

SAYRE ON THE SO-CALLED DOUBLE CONGENITAL DISLOCATION OF THE HIP-JOINT.—In a clinical lecture on this subject reported in the *Philadelphia Medical Times* for January 8, Dr. Lewis A. Sayre says that the nomenclature 'double congenital dislocation of the hip-joint' is entirely erroneous. In the first place, to have a bone *dislocated* it must first be *located*, and unless the bone has been located, he contends there can be no dislocation; there may be distortion and deformity, but a dislocation, double congenital, of both hip-joints has never yet occurred. One might as well speak of the *roof* of a child's mouth that has a cleft palate. The true pathology of this disease is, that there has been an arrest of

development in the bones which contribute to form the acetabulum; that, owing to this non-development, there is a fissured acetabulum; and it is through this fissure that the head of the femur glides upward on the dorsum of the ilium.

CROSBY ON THE FIRST RECORDED OPERATION FOR REMOVAL OF THE ENTIRE ARM WITH THE SCAPULA AND THREE-FOURTHS OF THE CLAVICLE. In the *New York Medical Record* for November 13, Dr. A. M. Crosby gives an interesting account of an operation performed by his father, the late Dr. D. Crosby, in which the whole upper limb was removed for a large osteo-sarcomatous tumour, involving the humerus, scapula, and clavicle. The record is made up partly from some hasty notes made by the operator himself, and from data furnished to Dr. A. M. Crosby by several persons, medical and un-medical, who were present at the operation. The following is an abridgment of Dr. Crosby's paper.

Jonathan G. Cummings, the subject of the report, was born in Plymouth, Grafton County, New Hampshire, August 7, 1800, and died July 6, 1838. He was by occupation a farmer, and at times followed the business of a stage-driver. During the first thirty years of his life he was unusually healthy. There was a family history of cancer.

Some time in 1833 or 1834 the patient drove his coach into Plymouth late at night; and, having previously wrenched his shoulder, fell asleep, with his arm hanging over the back of a chair. On awaking at daybreak, he found his arm numb and almost powerless; nor did it ever return to a perfectly natural condition. On the contrary, he suffered pain in the right shoulder, which persisted for two years, gradually attaining great severity, until it became constant.

About this time a hard tumour made its appearance on the anterior aspect of the shoulder, over the articulation. The tumour steadily increased, until it attained the size of a water-pail. It was so large that a slight inclination of the head brought the patient's cheek into contact with the tumour. The tumour was diagnosed as osteo-sarcoma. Operation was, however, regarded as too formidable to be undertaken, and was therefore declined, by Dr. R. D. Mussey, Dr. Amos Twitchell, and Dr. John C. Warren.

In January 1836 several openings formed, from which a thin, sero-sanguinolent fluid escaped. After this the pain diminished, but the discharge rapidly increased. A cavity formed, which was estimated to be about as large as a two-quart basin. There were twelve openings on the antero-superior aspect of the shoulder communicating with this cavity. Through these there was a copious discharge resembling colloid, but mingled more or less with pus, blood, and degenerated osseous tissue. The openings finally coalesced, forming one large one, about five inches in diameter. The discharge now ranged from a pint to a quart in the twenty-four hours. The opening being at the upper part of the cavity, the *débris* could only be removed by raising the body of the patient erect, and then bending the trunk far forward until the contents were evacuated. On one occasion the whole osseous framework gave way, leaving the arm hanging by the integument, muscles, etc.

The patient lost appetite and flesh, until he was reduced to the last degree of emaciation. Dr. D. Crosby was requested to see the patient. He ad-

vised him to have a radical operation attempted, to which the patient gladly submitted.

The operation was commenced with the expectation that the neck of the scapula and arm only need be removed; but on opening the joint freely, it was obvious that the entire scapula must be removed. After a moment's conference Dr. Crosby proceeded to remove the scapula, and the outer three-fourths of the clavicle. The flaps were antero-posterior. The operation and dressing of the wound consumed thirty minutes. At the end of the first fifteen minutes the patient lost consciousness, and became pulseless, with cold extremities, etc. He did not become fully conscious for twenty hours. He was delirious most of the night. Stimulants were freely used—twelve to sixteen ounces of whisky being given him during the night. The next day he appeared much better, and from this time gained strength rapidly. He began to sit up within two weeks, and got out of doors in seven or eight weeks after the operation.

In June following the operation, Cummings was to all appearance a healthy man. The cicatrix was fifteen inches in length, and seemed entirely free from induration. During July, however, the disease recurred in the cicatrix, and the tumour soon attained the size of a large teacup. This was removed by Dr. D. Crosby some time in August, and the wound cicatrised.

In the winter another tumour, not quite as large, developed in the cicatrix, and was removed early in 1837. No more tumours appeared, and in the following summer he was able to carry on his farm, working most of the time. He remained fleshy and in perfect health for a year. In April 1838 he was seized with an attack of paraplegia, from which he suffered until July 6, when he died, having survived nearly two years and four months. No necropsy was obtained; but Dr. D. Crosby always entertained the opinion that the paraplegia was due to a malignant deposit about the lumbar spine.

Dr. A. M. Crosby briefly enumerates the operations involving the removal of the arm, scapula, and more or less of the clavicle, in their chronological order.

R. D. Mussey reported in the *American Journal of Medical Sciences*, 1837, an operation involving the removal of the scapula and clavicle for malignant disease. Nineteen years before, he amputated at the metacarpus, and six years previously to the last operation, at the shoulder-joint. The patient was aged forty at the last operation, and thirty years afterwards he was living and in good health.

Amos Twitchell removed the entire arm, scapula, and part of the clavicle for malignant disease, but never reported it. His nephew, Dr. Geo. B. Twitchell, informs Dr. Crosby that the operation was performed in the winter or early spring of 1838. It was perfectly successful, but the patient died six months afterwards of the malignant disease.

Dr. G. McClellan removed from a boy of seventeen the scapula, arm, and part of the clavicle, with a fatal result. (*Principles and Practice of Surgery*, Philadelphia, 1848, p. 412.)

Gaetani Bey (*Memoirs of the French Academy of Medicine*) describes a disarticulation of the shoulder, with extraction of the scapula, and resection of the clavicle, in the case of a lad aged fourteen, who recovered.

In 1842 Professor Rigaud removed the scapula

and the outer end of clavicle eight months after amputation at the shoulder-joint. The disease was osteo-sarcoma, and the patient remained well three years after the last operation. (*Strasburg Medical Gazette* for 1844.)

In 1860 Niepce removed the left arm, scapula, and clavicle from a man thirty years of age, injured by machinery. The patient recovered. (*Bulletin of the Academy of Medicine*, 1864-5, vol. xxx.)

A. Lucke (*Archives für Klinische Chirurgie*, 1862) relates that Professor B. von Langenbeck, having exarticulated the humerus in the case of a man twenty-three years of age, on the recurrence of the disease extirpated the scapula and an inch and a half of the clavicle. The disease was osteo-sarcoma, and the patient survived eighteen months.

W. Busch removed the scapula and part of the clavicle from a young girl whose arm was previously amputated for cancer, and the patient recovered. (*Lehrbuch der Topographischen Chirurgie*, 1864.)

In 1863 Syme removed from Mr. K., aged forty, the arm, scapula, and portion of the clavicle. (*Excision of the Scapula*, Edinburgh, 1864.)

In 1864 G. Buck removed the scapula and part of the clavicle, the arm having been removed by a previous operation. The patient recovered from the operation, but died from a recurrence of cancer some months afterwards. (*New York Medical Journal*, 1869.)

J. S. Bird, in the *Lancet*, 1868, reports the case of Ellen L., injured by a fall, in whom two operations were performed in 1863-4. The head of the humerus, the entire scapula, and part of the clavicle were removed.

In 1867 Sir W. Fergusson removed from a man forty years of age, the arm, scapula, and part of the clavicle. A tumour, resulting from an injury, rendered the operation necessary, and the patient died on the third day. (*Medical Times and Gazette*, 1867; *Lancet*, 1867.)

Dr. P. H. Watson reports in the *Edinburgh Medical Journal* for 1869, 'an amputation of the scapula, along with two-thirds of the clavicle, and the remains of the arm.'

These are all the cases involving the removal of the arm, scapula, and more or less of the clavicle, that Dr. Crosby has been able to derive from the very extended researches of Drs. Rogers and Otis, which, he is inclined to think, have been nearly if not quite exhaustive.

BROWN ON FEMORAL ANEURISM, CURED BY DIRECT COMPRESSION, WHILE THE PATIENT WAS TAKING ACTIVE EXERCISE : DEATH FROM PERITONITIS SIX YEARS AFTERWARDS.—Dr. Buckminster Brown (*Boston Medical and Surgical Journal*, October 21, 1875), relates a very interesting case, which is well worth noting as a fresh example of the tolerance of pressure in some persons, though the treatment is not one which it would be desirable, or indeed possible, to imitate frequently.

The patient was a gentleman, aged thirty-eight, in good general health, in whom, without known cause, an aneurism of the femoral artery formed in the right groin, close to the commencement of the vessel. When first seen (in July 1863) the tumour was about three and a half inches in diameter, and was on the increase. Treatment by direct pressure was undertaken, the patient being confined to the bed and sofa, and ordered to keep a bag of shot, 10 lbs. in weight, applied over the tumour; and after a few

weeks a cannon-ball, at first of 12 lbs., and afterwards of 24 lbs., enclosed in a bag, and secured so as not to slip, was bandaged over the aneurism. Direct pressure was kept up in this way for several weeks more, the shot-bag and the two cannon-balls being interchanged during the whole of the day, the patient being at first relieved from the pressure during the night. A small pulsating swelling made its appearance in the course of the dorsal artery of the foot, but soon subsided under the pressure of an elastic apparatus. The whole limb was also enveloped in an elastic stocking; and after about three months of this treatment the shot-bag was applied during the night, also with a strong belt over it. This went on for at least a year and a half, and then he was allowed to walk about and attend to business, the tumour still pulsating, though feebly, and having become much harder, and the artery below the tumour being imperceptible to the touch. An apparatus of pad and bandage was securely applied to the parts, so as to produce 'a strong pressure on the tumour even during active exercise.' He began to attend to his business about two years after the first commencement of the treatment, in September, 1865. It was not till nearly four years afterwards, i.e. in May, 1869, or nearly six years after the first application of pressure, that the pulsation was found to have finally disappeared. Pressure was then gradually diminished, but not finally disused till April 1870. He lived till February 1875, when he was carried off by an accidental attack of acute peritonitis, the disease having no connection with the parts concerned in the aneurism. These were preserved, and the paper is accompanied by a drawing of the cured and consolidated aneurism, and of the main branches which carried on the collateral circulation. The aneurism was fusiform, commencing directly under Poupart's ligament, and extending through the whole length of the common, and about an inch of the superficial femoral. The external iliac was impervious for some distance above the aneurism. The profunda femoris seems to have been pervious, but no communication between it and the old aneurism could be found. The internal iliac and its branches were much enlarged, in order to carry on the circulation. The femoral vein was obliterated.

[The most interesting feature in this case is the great length of time during which the patient was able to tolerate direct pressure. Dr. Brown refers this to his exceptional power of enduring pain, for the pain connected with the treatment seems to have been severe and long-continued. The present reporter has not met with any other case in which so long-continued and so severe pressure has been borne, though the case of Verdier comes rather near it in this respect, in which a man who had had the thigh amputated for gangrene, caused by popliteal aneurism, and who had another aneurism in the stump, kept the latter in check for the four years, which he survived by pressure on the artery in the groin (*Lancet*, Sept. 5, 1874, p. 336). In that case, however, the disease, though checked, was not cured, and the pressure was made, not over an aneurismal sac, but on a healthy artery. But the two cases are so far parallel, as showing for how long a period a determined and not over-sensitive patient can bear compression. The reason why in the case before us Dr. Brown shrank from ligature or rapid compression of the external iliac artery, was the apprehension that there was extensive atheroma of the

arteries, an apprehension verified by the *post mortem* examination.

Another point of subordinate importance, but which is still interesting, is the large size of the anastomosis, by means of the comes nervi ischiadici, in connection with severe pain in that nerve, of which the patient had complained during life. A similar enlargement, though to not so great an extent, was found also in a branch running along the anterior crural nerve, and pain had been complained of in the course of this nerve also. The development of these collaterals was, in Dr. Brown's opinion, the cause of the pain.

The enlargement of the comes nervi ischiadici has been pointed out and figured by Porta and others (see Gray's 'Anatomy,' 7th edit., pp. 411, 412); but it is still doubtful whether this is really accompanied by any pain. In the present instance, the pressure and constrained position seem sufficient to account for pain in either or both of the large nerves of the limb.—*Rep.*] T. HOLMES.

MATERIA MEDICA AND THERAPEUTICS.

JACKSON ON SOME MEDICINAL PLANTS OF THE COMPOSITÆ.—The *Pharmaceutical Journal* for December 11, 1875, contains an article by Mr. John R. Jackson, on some medicinal plants belonging to the natural order Compositæ. He says that no natural order has such distinct botanical characters as have the Compositæ, and no other order, perhaps with the exception of Leguminosæ, has so wide a distribution over the surface of the globe. The properties of the order also vary considerably ; for while some species abound in a bitter aromatic principle, others are tonic and stimulant, while others again abound in a milky poisonous juice. Amongst official Compositæ included in the Pharmacopœias either of Britain or India are the chamomile (*Anthemis nobilis*), santonica (*Artemisia*, sp., probably a variety of *A. maritima*), elecampane (*Inula Helenium*), arnica (*Arnica montana*), dandelion (*Taraxacum officinale*), pellitory of Spain (*Anacyclus Pyrethrum*) and prickly lettuce (*Lactuca virosa*). Amongst other plants having medicinal properties, and which are occasionally used or have been recommended, may be mentioned the *Artemisia indica*, a plant with a strong aromatic smell and a bitter taste, occurring frequently on the mountains of India. An infusion of the leaves and tops of the plants are said to form a mild but efficient stomachic tonic and it has been administered successfully in nervous and spasmodic affections arising from debility. The common wormwood (*Artemisia Absinthium*) is too well known as the source of absinthe, to need more than a mere mention of its use for the preparation of that beverage. At one time it was very highly esteemed as a tonic, febrifuge and anthelmintic. It is said to impart a bitter taste to the flesh of sheep which feed upon it ; many of the species possess similar properties to the above, and are used in a like manner. The southernwood (*Artemisia Abrotanum*) for instance, at one time common in English gardens, and originally a native of the south of Europe, was formerly used as a tonic and vermifuge ; it was also considered to be obnoxious to insects and was often placed with clothes to keep away moths, the old French name of *Garde-robe* having arisen from this fact. The mugwort (*Artemisia vulgaris*), a well-known weed growing in hedgebanks in this country and distributed over Europe, North Africa, Siberia, Western Asia, to the Himalayas, was at one time strongly recommended as an emmenagogue. The dried leaves bruised, rubbed between the hands and formed into small cones, were considered a good substitute for Chinese moxa, which was prepared from *Artemisia moxa*. Under the name of wormseed, the herbalists sell the flower-stalks and heads of several species of *Artemisia*.

In the genus *Vernonia*, one of the largest of the Composite order, *V. anthelmintica*, common in

waste places throughout India, furnishes from its seeds by pressure a green-coloured oil or fat. These seeds are seen in most of the Indian bazaars; they are of a brown colour and have a bitter nauseous taste; amongst the natives they are highly valued as an anthelmintic, being bruised and administered in honey in doses of about a drachm and half, divided equally, and taken at an interval of a few hours, followed by an aperient. Their effect is said to be to expel the worms in a lifeless state. 'In Travancore, the bruised seeds ground up in a paste with lime juice are largely employed as a means of destroying pediculi.' They were regarded by Dr. Gibson as a valuable tonic and stomachic, and besides this they are also said to possess diuretic properties. From the evidence in favour of their use as an anthelmintic, they would seem to warrant further and more careful trials.

Another Indian plant, *Notonia gradiflora*, has been advocated as a remedy for hydrophobia. The manner of preparation and administration, as given in the Indian Pharmacopœia is as follows. 'About four ounces of the freshly gathered stems, infused in a pint of water for a night, yield in the morning, when subjected to pressure, a quantity of viscid greenish juice, which, being mixed with the water, is taken as a draught. In the evening a further quantity of the juice, made up into boluses with flour, is taken. These medicines are directed to be repeated for three successive days.'

The flowers of *Chrysanthemum Roxburghii*, also an Indian plant, have been used as a substitute for camomiles in India. The root when chewed imparts a sharp tingling sensation to the tongue, and it has been suggested that it might be used as a substitute for pellitory.

The genus *Eupatorium*, though at the present time furnishing no plants of really acknowledged medicinal value, was formerly considered of some importance, the common hemp-agrimony (*Eupatorium cannabinum*) being used for coughs, intermittent fevers, dropsy, etc. Externally it was applied in the form of a cataplasm to tumours, ulcers, etc., and the expressed juice mixed with vinegar was a favourite application in some forms of cutaneous diseases. For internal application it was recommended to boil a handful of the leaves and young tops in a quart of water or whey, which should be taken in frequent doses; or the expressed juice was also recommended in doses of from two to three ounces. The dried leaves were used in the form of tea, and the root boiled in water in the proportion of an ounce of the former to half a pint of the latter was administered in dropsies. It is described by Boerhaave as being in very great use amongst the turf-diggers of Holland, who used it in jaundice, scurvy, foul ulcers, and those swellings of the feet to which they are liable.

A South American species, *Eupatorium Ayapana*, is very aromatic and has a slightly bitter and astringent taste. It is generally used as an antidote for snake-bites both for inward and outward application. In Mauritius an infusion is made which is used in dyspepsia and generally in affections of the bowels and lungs. In the cholera epidemics which visited the island in 1854 and 1856 this plant, it is said, 'was extensively used for restoring the warmth of the surface and languid circulation.' The plant has become naturalised in India, Ceylon, and Java. In the former country the bruised leaves have been used successfully in the case of foul ulcers; a decoction is made and used as a fomentation. Though

the plant was formerly very highly extolled for its medicinal virtues, it has now to a great extent fallen into disuse; nevertheless, it is probable that upon further trial it might be found useful as a tonic, stimulant, and diaphoretic.

Several species of *Eupatorium* are used medicinally in North America, foremost amongst these being the thoroughwort, or boneset (*E. perfoliatum*). It is widely diffused, growing principally in damp situations; in the form of a warm infusion it is emetic, sudorific, and diaphoretic; but if taken cold it acts as a tonic and febrifuge. The leaves and flowers reduced to a powder are purgative even in doses of from ten to twenty grains. It is said to have been frequently prescribed with advantage in rheumatism, typhoid pneumonia, catarrhs, dropsy, and influenza. Porcher, in his *Resources of the Southern Fields and Forests*, tells us that the plant is extensively cultivated among the negroes on the plantations in South Carolina, as a tonic and diaphoretic in colds and fevers, and in the typhoid pneumonia so prevalent among them. He says, 'I have found this and the Senega snakeroot (*Polygala senega*) convenient and useful prescriptions; the latter with tartar emetic solution, to promote expectoration; and the former with flax-seed tea as a stimulant diaphoretic; combining them with spirit of turpentine when it has assumed the typhoid form. . . . The infusion of the roots and leaves is usually preferred, of which one to three ounces may be taken several times a day; of the root in powder, the dose is thirty grains. As an emetic and cathartic a strong decoction is used, made by boiling an ounce of the herb in three half-pints of water to one pint, given in doses of one or two gills or more.' Thoroughwort tea is used by many physicians in South Carolina in fevers, and is considered by them as the 'very best of the indigenous antiperiodics as a substitute for quinine.' Other species of North American *Eupatorii* having medicinal properties are the *E. purpureum*, purple thoroughwort, or gravel root; *E. tucrifolium*, wild horehound; *E. feniculaceum*, dog-fennel; and *E. rotundifolium*. The first possesses properties somewhat similar to *E. perfoliatum*; it is a diuretic, and one of the popular remedies for calculus. The second is tonic, diaphoretic, diuretic, and aperient, being commonly used in fevers and colds. The fresh juice of *E. feniculaceum* is said to relieve pain caused by the bites of insects, and it is sometimes strewed on floors to keep away insects. Though it seems doubtful whether the plant really contains any tannin, it attracted a great deal of attention in South Carolina in 1861, in consequence of its reputed power of tanning leather in an incredibly short space of time. The uses of *E. rotundifolium* are similar to those species already described.

At one time it was thought that the leaves of the *E. glutinosum* formed the matico of the Peruvians, but it has been proved since that the *Piper angustifolium* of Ruiz et Pav. (*Aritanthe elongata*, Miq.), is the source from whence true matico is obtained; several other plants, however, produce leaves similar in appearance to those of *Aritanthe*, and these leaves sometimes come to this country as matico.

Two or three species of *Erigeron* are used in North America as tonic and diuretic medicines. Foremost amongst these is the flea-bane (*E. canadense*). It is an annual plant, common in waste places in many parts of England, especially in the neighbourhood of London, having being originally introduced from the

United States, where in many parts it is frequent in sandy soils. It is frequently used in cases of dropsy and diarrhoea as a stimulant, tonic, diuretic, and astringent. The plant is much used by the herb doctors, who administer it in the form of infusion. An infusion of the powdered flowers is considered antispasmodic, and is used in cases of hysteria and affections of the nerves; an oil is also obtained from the plant, which is said to possess remarkable styptic properties. The frost root (*Erigeron philadelphicum*)—also a North American plant, as its specific name implies—has similar properties to the *E. canadense*, and has a great reputation for the cure of calculus and dropsy. Other species of reputed medicinal value in North America are *E. strigosum* and *E. pusillum*.

In the genus *Solidago*, which includes the golden rod of our thickets (*Solidago Virgaurea*), several species have reputed medicinal properties. The British species itself was formerly considered an useful medicine in diarrhoea and dysentery. The golden rod of North America (*S. odora*) is used as an aromatic stimulant and diaphoretic; it is said to lessen nausea, allay pain arising from flatulence, and to cover the taste or correct the operation of irritating or unpleasant medicines. It is said, when applied outwardly, to have the power of relieving pain arising from headache. The flowers, when dried, have been used as a wholesome and not unpleasant substitute for tea. Other species, such as *S. sempervirens* and *S. procera*, have reputed medical properties.

In the genus *Baccharis*, which includes a large number of species found principally in North and South America, many are of medicinal value; thus the Brazilians prepare from the stems of *B. trimera* an infusion which is used as a sudorific and tonic, while from *B. genistelloides* an extract is obtained used in cases of fever. In Parana, portions of the stems of *B. microcephala* are put into warm baths for the relief of rheumatism; and in North America, *B. halimifolia*, under the names of sea-myrtle or consumption-weed, is used as a demulcent in cases of consumption, and for coughs. It is somewhat mucilaginous, and has a bitter taste.

In America, *Ambrosia artemisiifolia*, known as the rag-weed, and *Ambrosia trifida*, the great rag-weed, are both used medicinally; the former as a substitute for quinine, and the second for arresting excessive salivation. *A. maritima*, a plant of Italy and the Levant, has a sweet smell and an aromatic bitter taste, and is said to be useful as a tonic.

The genus *Blumea* is remarkable for furnishing the peculiar camphor called Ngai camphor by the Chinese, well described by the late Mr. Daniel Hanbury in the *Pharmaceutical Journal*, (vol. iv. p. 709, 3rd series). *B. balsamifera*, the plant which furnishes this camphor, is said to be in very general use in Java and China as an expectorant, and in Cochin China as a stomachic, antispasmodic, and emmenagogue. Other Indian species, as *B. lacera* and *B. aurita*, are said to have a strong smell of turpentine, and to be used by the natives in dyspepsia.

Eclipta prostrata, also an Indian plant, common in wet places, is described as being purgative and emetic, these properties residing particularly in the roots. *E. erecta* and *E. procumbens*, both North American species, yield a dark or black dye used for dyeing the hair.

Besides those above enumerated many other plants

belonging to this order are used in various parts of the world for their medicinal properties. We have pointed principally to the plants of America and India, these being countries in which the properties of the plants would most likely be discovered or experimented upon by Europeans. We have far from exhausted the list of either country, nor have we introduced those of acknowledged utility, such as *Taraxacum*, *Lactuca*, and others which grow equally well in India and America as in England; neither have we included British plants, which formerly appeared in herbals, but which are now no longer used.

FAYRER ON THE EFFECTS OF ARNICA AS A LOCAL APPLICATION.—Dr. Fayer writes in the *Practitioner* for January, that, when deer-stalking in September, he sprained his wrist rather severely, by stumbling in a hole. In the evening he applied a weak solution of tincture of arnica, enveloping the lint soaked in the solution with a piece of oiled silk. This was removed after two or three days; the pain of the sprain having abated, and the swelling subsided. The moisture of the application had, meanwhile, caused a few small papules to appear on the skin. These quickly disappeared, and the surface seemed sound. About six days later he came into contact with a nettle, which stung the wrist very slightly. On the same evening violent irritation of the part set in, and the skin of the wrist and forearm, exactly corresponding to the early application of the arnica, became hot, painful, and affected with an intolerable itching and burning sensation. The following day, the skin was much inflamed, and the pain extended up the arm to the axilla, the absorbents being very painful. The skin was red, brawny, and covered with eczematous patches.

Rest, purgatives, and the application of acetate of lead to them gave relief; and the next day the acute symptoms had subsided, but leaving the wrist still swollen, brawny, and painful, with irritating spots of eczema, which gradually dried into scales.

He remarks that this case not only confirms the statement that arnica has the property of producing irritation of the skin, but shows the necessity of caution in applying it and of limiting the time of its application.

PAUL ON PETROLEUM AS A DRESSING FOR ULCERS AND SUPPURATING WOUNDS.—Dr. Comegys Paul (*Philadelphia Medical Times*, Dec. 27) makes some observations upon the use of petroleum as a useful and cheap surgical dressing. It seems to him to combine very especially the two properties of being antiseptic and stimulating. The ordinary commercial petroleum can be applied with little trouble or inconvenience; and, in cases where the surgeon is not prepared with his liniments and cerates, it can be used without subjecting him to delay and waste of time. That petroleum is antiseptic we have most excellent authority.

In a case of extensive destruction of the cellular tissue in the arm of an Irish labourer, about fifty years of age, he used it with great benefit. A young woman convalescent from typhoid fever, through the carelessness and neglect of the nurse, formed a large sacral ulcer with a slowly separating slough and marked diminution of the vitality in the surrounding parts. It was dressed with petroleum alone,—lint saturated with the oil being packed into the entire cavity, and the whole

retained by adhesive strips. It healed in a month, and at no time was there a bad smell or discharge of any account.

Further instances of the successful employment of petroleum might be cited, but only to detail similar results. Dr. Paul believes the petroleum to be most useful as an application to non-specific sluggish ulcers, and to all suppurating wounds that have a tendency to heal with an unhealthy and easily-ruptured cicatrix. He has not tested its utility in recent wounds or after surgical operations.

As an injection in sinuses, either connected or unconnected with diseased bone, the result will be satisfactory. In a bone-sinus it can be used without interruption, materially diminishing the discharge.

It is valuable in all inflammations of an erysipelatous character, being applied like an ordinary fomentation. The spreading of the disease is, apparently, favourably influenced, and the duration shortened in many cases.

Wounds dressed with petroleum should be thoroughly cleansed, then covered with saturated lint, and, where there has been deep-seated destruction of the tissues, charpie fully impregnated with it should be packed into the cavities, and the whole overspread with oiled silk, waxed paper, or a piece of muslin spread with lard.

The smell is not at all oppressive, but is generally concealed by the covering, and does not cling to the fingers after ablution. The very decided objection to carbolic acid, the odour of which remains for hours about the person, is entirely avoided in using petroleum. The very little pain or smarting sensation which sometimes occurs at the moment of application subsides in a few moments.

CLELAND ON THE USE OF SACCHARATED LIME IN TYPHUS FEVER AND OTHER COMPLAINTS.—Dr. Cleland, of Galway, in the *Practitioner* for December, says that it is eighteen years since, in the *Edinburgh Medical Journal*, he called the attention of the profession to the medicinal properties of saccharated lime. He has often been struck with the utter misconception of the properties of this substance, which is prevalent, and prevents its being used so much as it should be. The two points most necessary to insist on in the administration of this remedy are probably large doses and copious dilution. A teaspoonful of the pharmacopœial 'liquor,' given after meals, is necessary, in most cases, to develop its effects as a stomachic, and should be diluted in three or four ounces of water; but in cases in which there is foulness of the tongue from acute causes, much the best plan is to fill a tumbler with water, introduce as much of the solution of lime as can be added without giving a very disagreeable taste, and let the patient drink of the mixture *ad libitum*; and when one tumbler is finished let another be filled. Generally, he believes, in most cases in which there is great foulness of the tongue, this treatment will be found most advantageous. It is not suitable, however, when there is inflammation of the stomach, or great irritability, indicated, for example, by central redness of the tongue, with sharp ragged edges. Attacks of bilious or gouty diarrhœa and British cholera yield with great rapidity to the free use of saccharated lime; and it is found exceedingly grateful by the patient on account of its alleviating the dry uncomfortable feeling in his mouth. It produces usually copious diuresis, a gentle perspiration, and relief from tormina, while

the violence of the action of the bowels is quickly mitigated. There is never, however, the slightest constipation produced, the action of saccharated lime being slightly aperient, and even in some persons markedly so.

In many instances he has had occasion to observe that when an hospital patient had a black, parched, and cracked tongue, like a cinder, with the teeth and lips black with sordes, saccharated lime being administered freely, the tongue was moist the following day, and in a few days the black crust had entirely loosened and disappeared. The cases to which he alludes have all been cases of typhus, no typhoid cases having come into the Galway Fever Hospital during the past year, nor for some time previously. In these circumstances, although he has tried saccharated lime in typhoid fever, he is not prepared to make any statement with reference to its utility in that particular disease; but in any case of black parched tongue, no matter what the disease, he should rely on its effects. It is even beneficial where that symptom exists from urinary causes. In typhus he gives the lime in milk, instead of water. Given in this way it has the advantage of preventing that peculiar sensation in the mouth which is liable to follow the drinking of milk, and make it unsuitable for quenching thirst. Thus the patient is induced to take a certain amount of mild nutriment when he is most prostrate. Within the last year, of sixteen females admitted to hospital, suffering from typhus, and treated by Dr. Cleland, only one died; and that one was an aged woman with her tongue parched and blackened to a cinder, and within a few days or the fever running its course when she was admitted; yet she speedily revived, and when at last she succumbed, after several weeks, it was under the effects of exceedingly extensive bedsores, which had commenced before her admission. In no case does he impute to the saccharated lime effects which might rather be considered due to stimulants.

CLELAND ON THE USE OF LIQUOR BISMUTHI FOR HÆMORRHOIDS AND PROLAPSUS ANI.—In the *Practitioner* for January, Dr. Cleland, of Galway, recommends the use of liquor bismuthi given in enema in cases of hæmorrhoids and prolapsus ani. His attention was first drawn to the remedy by a rather peculiar case of prolapsus of the bowel in a middle-aged woman, in whom, whenever she parted her thighs, the bowel emerged and hung down for about six inches, in folds of such a character as made it evident that at least half a yard of intestine was extruded. All previous treatment had failed. It appeared probable that an irritated and congested condition of the mucous membrane led to a derangement of the action of the muscular walls rather than that in a strong woman, a local relaxation, involving the sphincters and intestinal walls, had produced a prolapsus, which led to congested mucous membrane from exposure. Ointment or powder obviously could not be effectually applied; but, as the liquor bismuthi in stomach-affections has a soothing influence far superior to white bismuth, Dr. Cleland directed the patient to mix a dessert spoonful of liquor bismuthi with half a wine-glassful of starch, and, after getting into bed and returning the bowel to its place, to introduce this enema and retain it. A few weeks afterwards, the woman reported that she was nearly well. Dr. Cleland has since frequently used the same remedy for the ordi-

nary prolapsus in children, with invariable and rapid success.

In severe hæmorrhoids, when the mucous membrane is considerably involved, Dr. Cleland knows no application to compare with injection of liquor bismuthi, which has the advantage of being painless; and, as in the case of prolapsus narrated above, the improvement of the mucous membrane has a wonderful influence on both the veins and integument.

MILLS ON OXALATE OF CERIUM.—Dr. C. K. Mills, in an article on the oxalate of cerium, read before the Philadelphia County Medical Society, and published in the *Philadelphia Medical Times* for January 8, gives the following account of cases in which he has used this remedy.

	No. of Cases.	Permanent Relief.	Improvement.	Failure.
Nausea and vomiting of pregnancy	11	10	1	—
Nausea and vomiting of uterine disorders	3	2	1	—
Nausea and vomiting of hysteria	5	4	1	—
Vomiting associated with neuralgia	2	1	1	—
Vomiting of phthisis	2	—	1	1
Vomiting of typhoid fever	4	4	—	—
Vomiting and diarrhoea of dentition	5	5	—	—
Dyspepsia	15	6	7	2
Diarrhoea	3	1	—	—
Dysentery	1	—	—	1
Gastric ulcer	5	—	3	2
Chronic gastritis	2	—	1	1
Scirrhus cancer of pylorus	1	—	—	1
Enteritis	1	—	—	1

The nausea and vomiting of pregnancy almost always yielded with promptness to a few doses of the oxalate of cerium; and by a continuance of the remedy the symptoms could be kept in check. Two of the cases relieved would come properly under the grave vomiting of pregnancy; the rest were the ordinary simple form of nausea and vomiting. In some cases the benefit afforded was magically prompt. Occasionally relapses occurred; but a recurrence to the drug soon set matters right again.

In the nausea and vomiting and irritable stomach often found associated with amenorrhœa, dysmenorrhœa, prolapse, flexions, and other disorders of the uterus, and with hysteria dependent upon psychical and general physical causes, such as grief, care, anxiety, overwork, and the like, the oxalate of cerium is a very efficient remedy.

In two cases of vomiting, associated with severe facial neuralgia (not migraine), the oxalate was prescribed with success, in one instance relieving the symptom entirely, the neuralgia also disappearing without other treatment; in another the vomiting was checked on several occasions, but galvanism had to be used for the removal of the neuralgia.

He gave the oxalate in two cases of obstinate vomiting occurring during the progress of phthisis; in one of which it effectually stopped the vomiting, but in the other failed. According to Dr. George B. Wood, the obstinate vomiting of phthisis is sometimes the result of chronic gastritis, the signs of which can be found after death; whereas in other similar cases no marks of inflammation can be discovered, the disorder of the stomach being simply functional or reflex. It is probably in the latter class of cases that the remedy proves most useful.

Vomiting and sickness of the stomach are symptoms sometimes present at various stages of typhoid

fever, and in four cases of this kind the oxalate of cerium afforded prompt relief. One of these cases was complicated with pregnancy of seven months' duration, the vomiting being exceedingly obstinate. Another very grave case was entirely relieved of the vomiting, but died a few days later from the effects of a violent purge administered without orders. Three of the cases recovered.

Small doses of the oxalate of cerium, about the one-fourth of a grain, given early and often in cases of vomiting and diarrhoea attendant upon the evolution of teeth in infants, are highly efficacious. Besides the cases given in the table, Dr. A. K. Minich has used the oxalate of cerium with striking success in ten cases of these intestinal disorders of infants and young children. It seems to act well in those cases in which bismuth, pepsin, or opium is sometimes beneficial.

Fifteen cases are classed in the table as dyspepsia, of which six were permanently relieved, seven improved, and two unsuccessfully treated. The cerium salt seemed to act with most efficacy in those cases in which morbid sympathetic influences, so called, played an important part in producing the indigestion, probably where depressed or deranged innervation of the stomach existed. It might, perhaps, be advantageously used with the bitter tonics.

The case of diarrhoea in which the oxalate of cerium proved successful was due to nervous excitement. The two cases palliated were the result of indigestion.

In dysentery, gastric ulcer, chronic gastritis, pyloric cancer, and enteritis, Dr. Mills's experience with the drug under consideration has not been very encouraging; but, as in some cases it palliated severe symptoms, it is, he thinks, worthy of a more extended trial.

The exact mode in which oxalate of cerium produces its effects has not with certainty been determined. Dr. Mills says that it seems to have the power of diminishing the reflex excitability of the alimentary tract. It does not seem to answer so well in cases of inflammation or structural lesion of the digestive canal.

The insolubility of the oxalate of cerium is not absolute proof that its operation is simply mechanical. It may be true as a general law that insoluble bodies are not regularly absorbed; yet, directly or indirectly, they sometimes appear to bring about constitutional impressions. It is quite possible that a preparation which is insoluble out of the body may dissolve in it under the stimulus of active digestion, or a chemical circulation may perhaps take place through the tissues. A portion, at least, of the effects of some remedies seems to be due to their direct operation upon the superficial nerves of the stomach.

The dose of oxalate of cerium for an adult is from one to five grains; for an infant or small child, from one-fourth to one-half a grain. Dr. Mills has given as much as six grains, but has most usually prescribed it in doses of two or three grains. In two instances in which it was ordered in doses of five and of six grains, it appeared to cause slight gastric uneasiness and diarrhoea; but these may have been accidental occurrences. It is most readily administered in the form of powder or of pill. If powders be prescribed, it may be given alone, or rubbed up with sugar of milk, powdered gum arabic, gum tragacanth, or some similar article. By trituration the fineness of the commercial oxalate, and of the chemically pure from acid solution, can be much in-

creased; and he believes that they act more promptly after they have been submitted to this process. It may be made into pills with any of the vegetable extracts, such as extract of gentian, quassia, lupulin, hyoscyamus, etc.; or, if it be desired to give it alone, the pills may be made up with syrup of acacia, glycerin, or concentrated honey. Its insolubility renders its administration as a liquid preparation generally unadvisable, but it may be suspended pretty well in mucilage of acacia and simple syrup.

LOOMIS ON MORPHIA IN ACUTE URÆMIA.—The *Philadelphia Medical and Surgical Reporter* of Jan. 8, says that, in his late work on *Diseases of the Respiratory Organs*, etc., Professor Loomis states that, as the result of his experience, he holds the following opinions. 1. Morphia can be administered hypodermically to some, if not to all, patients with acute uræmia, without endangering life. 2. The almost uniform effect of morphia so administered is, first, to arrest muscular spasms by counteracting the effect of the uræmic poison on the nerve-centres; second, to establish profuse diaphoresis; third, to facilitate the action of cathartics and diuretics, especially the diuretic action of digitalis. Thus morphia administered hypodermically becomes a powerful eliminating agent.

The rules which are to govern its administration are as yet not well defined. His own experience would teach him to give small doses at first. If convulsions threaten, and a small dose do not arrest the muscular spasms, it may be increased to twenty minims, and the hypodermic injections may be repeated as often as every two hours. It must be given in sufficient quantities to control convulsions; neither the contraction of the pupils nor the number of the respirations is a reliable guide in its administration.

FISKE ON THE THERAPEUTIC USE OF ANILIN.—In the *Pacific Medical and Surgical Journal*, quoted in the *Philadelphia Medical and Surgical Reporter*, December 18, 1875, Dr. H. M. Fiske states that Dr. Justin, of Marseilles, finds anilin a valuable remedy in chorea. In one case the physician had given iron, quinine, and strychnia, valerian, and the multitude of remedies usually prescribed in such cases. But the spasmodic movements grew worse instead of better, and, in despair, the patient consulted Dr. Justin. On her being brought into his presence in an invalid's chair, he noticed the general cachectic and dreary appearance of the countenance, as indicating tuberculosis and muscular degeneration, common in the youth of that sunny clime.

The spasmodic movements were so great that she could hardly be retained in her chair, the least air or disturbance renewing them. He bethought himself of anilin, as one of the products of the coal-tar, and gave it in one-grain doses, four times a day, in pills, in connection with extract of gentian, directing the patient's bowels to be kept open with a pill, made after the following formula, one which he had found very useful in chronic constipation of adults:—

R. Nitrate of bismuth,	grs. xx	
Sulphate of alumina,	grs. xxx	
Extract of gentian,	q. s.	M.

To be made into 20 pills; one to be taken night and morning.

These were given so long as the constipation lasted, which was about two weeks.

The anilin at first produced a little nausea, which

soon subsided. After the fourth day of treatment it was continued with camphor, made into pills, one grain each. In two weeks the case was cured. Dr. Justin reports several cases in which like results followed. Dr. Peter Jones, of Terra Haute, Indiana, has also used it, with like success, in several cases, notably one which had continued for fifteen years. Dr. Aaron Wilson, of Nachitoches, has also used it, especially among the negro population, and with marked success. It is best to commence with half-grain doses of the medicine, gradually increasing, till two grains are given for a dose. Of the sulphate, three or four grains, gradually increased to eight or ten grains, may be used. It frequently produces a blueness of the skin, which soon passes away, and need not create any alarm.

MILLER ON THE FORM OF ALCOHOL TO BE USED MEDICINALLY.—In the *American Journal of Pharmacy*, Mr. A. W. Miller says:

Raw corn whisky or high wine, such as is used for the manufacture of alcohol, is undoubtedly strictly pure, as there is no incentive whatever to its adulteration. Nevertheless, many vile epithets, such as Jersey lightning, rot-gut, etc., are heaped upon this, simply because it is lacking in smoothness, oiliness, and body; so that it meets with little favour among those who are sufficiently familiar with it to recognise at once its want of age.

In the asthenic forms of many diseases, it is of prime and often even of vital importance to administer alcohol. Nothing as yet known so well substitutes the functions of food, and thus bridges over the chasm of greatest prostration, during which the system would otherwise inevitably succumb.

While we cannot and dare not dispense altogether with a drug of such inestimable value, what is there to be gained by running the unnecessary risk of inculcating a taste for the truly fragrant bouquets of choice French brandy, or the almost equally precious old Kentucky Bourbon? We can well afford to dispense with this meretricious and alluring *haut goût* of liquors, which, even in their purest state, are but too apt to win boon companions, ready and willing to follow their enticing solicitations.

The economic aspect is another strong point in favour of the introduction of plain rectified spirit into use as an official medicine.

We may sum up as follows. Rectified spirit is almost always strictly pure, while the more expensive liquors invariably contain fusel oil, and very frequently other impurities. While the taste and odour of rectified spirit is not so tempting as that of the choice cabinet liquors, it is entirely free from the disgusting smell and flavour of the ordinary diluted alcohol.

LEVI ON THE ACTION OF ERGOT.—In a paper in *Lo Sperimentale* for August and September 1875, Dr. G. Levi discusses the action of ergot on the uterus. He relates experiments made on bitches, in which contraction of the uterine muscular fibres was produced by the administration of phosphoric acid, in doses of from ten to twenty drops. Dr. Garzella also found uterine contractions to be produced in two cases in women by the use of fifteen drops of officinal phosphoric acid in water, taken in three doses. Dr. Levi arrives at the following conclusions. 1. The therapeutic effects of ergot are due to the presence of phosphoric acid. 2. The diseases in which ergot is an useful remedy derive equal benefit

from phosphoric acid. 3. In ergot, two distinct series of phenomena are produced by different elements: physiological (ergotism), by the vegetable principles (ergotin, ecbolin, etc.); obstetrical, by phosphoric acid. 4. The hæmostatic and erbolic effects are produced with equal intensity and readiness by phosphoric acid and by ergot. 5. The quantity of phosphoric acid found by analysis in recently powdered ergot, in old powder, and in the aqueo-alcoholic extract (ergotin) is proportionate to the obstetric effects produced by these substances respectively. 6. The results of these researches are confirmed by clinical reasoning.

DE SABBATA ON THE TREATMENT OF DIPHTHERIA WITH ACID SULPHATE OF IRON.—In the *Annali di Chimica applicata alla Med.*, October, 1875 (quoted in *Giornale Veneto delle Scienze Mediche*, December) De Sabbata says that, during a severe epidemic of diphtheria, he used an acid solution of sulphate of iron for gargling and for application by means of a hair-pencil. The formula for gargle was: pure sulphate of iron 5 grammes (77½ grains), dilute sulphuric acid 25 drops, water 100 grammes. For local application, the solution was a little stronger (70 or 80 parts of water instead of 100). He says that this solution completely destroys the characteristic sloughy odour, and removes the eschar in the submucous tissue, while carbolic acid only masks the odour and does not arrest the diphtheric process. He has treated forty cases in this way, giving also internally hyposulphite of soda and tannate of quinine. In these cases, the mortality was at the rate of 12½ per cent.

HUSEMANN ON THE ACTION OF SQUILLS.—In the *Deutsche Medicinische Wochenschrift*, no. 13, 1875, Dr. Husemann, of Göttingen, describes experiments which he has made on the action of squills, and arrives at the following conclusions. 1. The extract of squills of the German Pharmacopœia is very constant in its action on the animal organism. 2. The action on the nerves and muscular structure of the heart is similar to that of digitalin, digitalein, helleborein, antiarin, and other so-called cardiac poisons. 3. The diuretic action of the extract of squills can only be explained by its producing increase of the blood-pressure in conjunction with its action on the heart. 4. The indications and contraindications for the use of extract of squills in dropsy do not differ essentially from those of digitalin. 5. The extract of squills is not an expectorant. 6. It is not an antipyretic; there is, on the contrary, a constant rise of temperature both with large and with small doses. 7. The scillitin of the shops is uncertain in its action; hence its dose cannot be accurately determined, and it is not to be recommended as a substitute for extract of squills.

BONALUMI ON SUBCUTANEOUS INJECTION OF TINCTURE OF IODINE IN GLANDULAR SWELLINGS.—Dr. G. Bonalumi sums up a paper on this subject as follows (*Giornale di Medicina Militare*, November 1875, and *Gazzetta Medica Italiana-Lombardia*, March 4). 1. Parenchymal injections of tincture of iodine have a decided effect in producing reduction of glandular swellings of the neck and groin, which are common in soldiers. 2. The injections are also useful even when there is suppuration, especially if the pus be removed by aspiration, and the abscess

injected with a detergent fluid. 3. The best effects are produced in single swellings, not too old. The existence of ulceration of the capsule of the gland is a contrary direction to the use of this remedy. 4. This method is to be preferred to those hitherto employed on account of its harmlessness, the ease with which it is carried out, and its applicability to all patients. 5. Luton's plan of treatment is not only useless, but injurious, in scrofulous deposits in the neck, and it is useless in chronic hyperplasia of the tonsils and in lipoma. A. HENRY, M.D.

FRANCHIS ON CHLORIDE OF ZINC IN SOME CUTANEOUS AFFECTIONS.—In the *Paris Médical* for February 17 there is a notice of a paper by Dr. Franchis, in which he gives a *résumé* of eighteen cases of skin-eruptions treated by Dr. Lailler at the Hôpital Saint-Louis with chloride of zinc. The diseases were scrofulides and ulcerating syphilides. The author shows that chloride of zinc acts as a powerful modifying agent in lesions of this nature. He saw in many cases where tincture of iodine and acid nitrate of mercury were powerless to stop the ravages of syphilitic ulceration, that deliquescent chloride of zinc, employed with a brush on the edges of the ulcer, arrested it immediately.

VERNEUIL ON SULPHATE OF QUININE IN PAIN.—In one of his recent clinical lectures (*Paris Médical*, February 17) M. Verneuil took occasion to mention the fact of a woman afflicted with cancer of the uterus, with intolerable pain, which prevented her from sleeping. Narcotics having failed, and M. Verneuil having noticed that the pains were worse every second day, the surgeon prescribed sulphate of quinine in the dose of 0.50 centigramme. The same dose was continued for several days; the patient was able to take rest, and ultimately the pain disappeared. It results from these observations of M. Verneuil that quinine acts efficaciously, in concert with narcotics, in soothing the pains of uterine cancer; at the same time, there is no reason to attribute a paludal origin to these pains. W. DOUGLAS HEMMING.

THE HUNYADY JÁNOS WATERS.—There is a class of mineral waters which are rarely drunk at the places where they rise, but which are largely exported. They are called by the Germans bitter waters, on account of the taste which they have of Epsom salts. In England we have waters of this class, for instance, at Streatham, but they are not strong enough. These waters are all aperient, and their value has long been acknowledged. Thus the true Seidlitz water (what passes under the name of Seidlitz powder bears no resemblance to it) was long known in England as a fairly convenient aperient; but its chief ingredients, about 13.54 parts of sulphate of magnesia in 1,000 parts, were not sufficient to make it quite powerful enough. Two other waters of the same class, the Friedrichshall and Püllna, were imported from Germany some years ago, and have been much used in England, being superior to the Seidlitz water; and recently a Hungarian water, called the Hunyady János, has been introduced, which bids fair to be the most popular of all. The chief contents of these three waters will be at once seen by a glance at this table, which shows the relative amount of their salts in 1,000 parts:

	Friedrichshall.	Püllna.	Hunyady.
Sulphate of magnesia .	5'1	12'12	16'0
" soda .	6'0	16'11	15'9
Chloride of sodium .	7'9	—	1'3
" magnesium .	3'4	—	—
Total: including all constituents .	25'19	32'7	35
Relative proportion of carbonic acid free and half combined .	166'3	69	278'5

It is obvious that Püllna and Hunyady are the two richest in sulphated purging salts, while Friedrichshall contains a considerable amount of chlorides. None of these waters contain much carbonic acid, though the Hunyady has most, and has the advantage of containing a minute portion of carbonate of soda, amounting nearly to 1 part in the 1,000.

Of these waters the Püllna and Hunyady are, as might be conjectured, the most active aperients, the purgative power of small quantities of the chlorides not being great.

Aperient waters of this class are used in two ways; first, as ordinary purgatives, like a dose of medicine, when they are given in full single doses; secondly, to correct the habit of constipation, when they are given in small doses for a considerable period.

For the first purpose, on an average about half as much is required of the Hunyady as of the Friedrichshall, and very distinctly less than of the Püllna. The water of the Hunyady is mild, and of a comparatively pleasant taste, acts rapidly, and usually without almost any griping. It produces first soft and then copious watery motions. It increases the secretion of bile, but is not known to alter its quality. It diminishes the amount of urea and of water, and less nitrogen is excreted from the system.

For the second purpose, that is, for overcoming habitual constipation, the Friedrichshall has been the favourite in Germany. It is generally thought the least lowering, but is bulky, and not very certain in its operation. Püllna in smaller doses answers extremely well, and although its continued use is described as lowering, I have never seen any harm from its use extended over long periods. Hunyady water may be used in the same way, and there is no doubt of its efficiency, although there is not as complete evidence of its action in these small continued, as in its larger doses.

It is only thirteen years since the Hunyady water was discovered. There are six springs close to each other near Buda, with water of almost identical composition, and these waters are mixed together to form the water which goes by the name of Hunyady János. Its constituents do not vary in amount, as those of the Püllna are said to do.

All the first physicians of Germany have made extensive trial of the Hunyady, and have declared that it is the most certain and the most comfortable in its action of all the aperient waters. The special indications for its use are, in costiveness, especially in that of pregnancy, in portal congestion with tendency to hæmorrhoids, and in sluggish action of the liver.

A half or a full wine-glassful of the Hunyady water taken at bedtime produces a couple of soft motions next morning. One or two wine-glassfuls taken in the morning fasting, produce four or five motions, at first soft, afterwards watery. It is most efficacious when taken at a temperature not below 60°.

It is very evident that this convenient and sure

purgative, of whose action it is so easy to limit the extent, is a very valuable addition to our remedies; such a medicine may come into play in the treatment of almost any affection. It is not surprising to learn how extended its use is in southern Germany, and that its employment is rapidly spreading in England.

PSYCHOLOGY.

BRUNET ON THE CONTAGION OF INSANITY.—Dr. Brunet (*Annales Médico-Psychologiques*, 1875) has published a paper on the contagion of insanity.

After quoting almost every French alienist in support of these observations, Dr. Brunet mentions two cases in other journals—*Le Droit* and *Le Moniteur de la Côte-d'Or*.

Next follow descriptions of three cases observed by the writer himself, illustrating the theory of the contagion of madness.

The first case, which possesses a medico-legal interest, is thus summarised. Two brothers charged with arson—transmission of insanity from the elder to the younger—hereditary predisposition—trial in the Court of Assize—acquittal.

OBSERVATION I.—*Medley of Delusions of Grandeur and of Persecution—Hallucinations of Vision, Hearing and Smell—Stupor—Tendency to Dementia.*

Case 1.—Jean P., elder of the two brothers, aged twenty-eight, was admitted to the asylum of Breuty on February 24, 1874.

A sister was eccentric; a maternal uncle was insane from the age of twenty-three; a paternal uncle was also insane, and this uncle had had an imbecile son. The parents of the patient were below the average in intellect. The patient had had a previous attack at twelve years old.

On the night of January 2 or 3 (about two months before admission) he had set fire to his house, with the assistance of his younger brother. There was no apparent motive for the crime, as the brothers were in good work at the time, and had amassed not less than 600 francs by their industry. They lived almost completely isolated, and scarcely recognised their nearest neighbours. Their earnings were intentionally left to burn in the flames of the house. They voluntarily gave themselves up to justice, alleging, as an excuse for the act, that they had been terrified by the apparition of an enormous caterpillar in the chimney, which they fancied to be Death, and which they had wished to burn, fearing that it would carry them off.

There was a suspicion that intemperance had caused this demonstration of eccentricity.

On February 5, the day before the trial, the younger brother tore his clothes, became incoherent and stripped himself naked. This brother was sen

o the asylum of Breuty, to ascertain whether or not he was feigning insanity.

On February 18, Dr. Machenaud signed a certificate committing this patient to an asylum.

Both the brothers, during the period they were awaiting their trial, had affirmed that they had no other motive for setting fire to their house except the fear of the caterpillar in the chimney, which they also declared was full of spiders.

Twenty-four hours after admission, the brother Jean further asserted that he was God, and that he had, by setting fire to his house, destroyed Death, and that in consequence no one would ever die again. He had, moreover, delusions of grandeur mixed up with incoherence of language. Delusions of suspicion and an attack of acute maniacal excitement were developed subsequently, and he further confessed to having seen the spirit of an absent brother, who was in the army, drilling a regiment of mules on a common. Two attempts to escape, further suspicions of poisoning, and eating fæces, were the next symptoms noticed. A condition of acute dementia, uninfluenced by electricity or other stimuli, and a refusal to speak, were the chief points observed during the next four months.

May 1. He was removed for a further trial.

OBSERVATION II. (upon Clement P., the brother of the above patient)—*Intermittent Excitement—The same Delusions as his Brother—Recovery.*

He was admitted to the asylum of Breuty February 6, 1874.

Feb. 7. He was excited and incoherent. He had been singing all night.

Feb. 10. There were onanism and a delusion that he had set fire to his house to destroy Death, who had appeared to him as a yellow caterpillar. Neither he or his brother concerned themselves about the loss of their furniture. He confessed to habits of intemperance, but was not aware that he was said to be insane, or that he was in an asylum.

March 2. He tore up his blanket because it was of a green colour, saying that he ought to have one of the natural colour of the wool. His brother had also the same idea. He declared he was God, and had suspicions of being poisoned.

May 1. He was in a condition of acute mania. He was removed for further trial at the Assizes Court. Drs. Brunet, Eyriaud, and Machenaud declared the prisoners to be both insane.

May 5. The brothers were tried at the Assize Court. Drs. Brunet and Eyriaud gave evidence that they believed the prisoners to be insane on the following grounds.

The eldest brother had exhibited symptoms of dementia impossible for any one to feign. The younger had had several attacks of maniacal excitement, with fetor of breath, heat of skin, and acceleration of pulse, about the nature of which there could be no doubt.

Dr. Brunet affirmed that he believed that the insanity had been communicated from the elder to the younger brother—the elder having had a previous attack at twelve years old; that they were predisposed to this affection by their hereditary antecedents; that the life of isolation, the excess of drink, and the onanism easily explained the access of the malady in these two brothers.

Dr. Eyriaud gave similar evidence, and both prisoners were acquitted and sent back to the asylum at Breuty.

[A few remarks on this novel theory of the conta-

gion of insanity may perhaps be not out of place here.

Anyone who has studied the habits of the insane is aware that one patient will frequently imitate the actions, gestures, and even the language of another. In certain forms of acute mania, the patient will repeat the last words anyone near him may have said, mixed up with his own incoherence. But it must be confessed that for one patient to imitate the delusion (or hallucination in this case) of another is something quite new to us. It is true that sometimes several melancholiacs will refuse food on the same day under the same delusion that it is poisoned; but if we inquire into the details of such delusions, we shall find that they differ. One man believes that the doctor is poisoning him, another that his relations are doing so, and a third that evil spirits are conspiring against him.

We could have wished Dr. Brunet had been a little more clear in his account of these two cases. We should like to know if the delusion about the caterpillar was first announced by both brothers when in one another's company, which would prove the contagion of the delusion, or if this same delusion was elicited subsequently upon medical examination of the brothers separately. If the latter, the case would still be one of great psychological interest. For it would illustrate the fact that two brothers, similarly constituted in their bodily and mental organisms, had simultaneously and independently propagated this same extraordinary delusion.

We should also like to be informed whether or not the two brothers were kept separate in the asylum. We find the same delusion there developed in both cases—that a green blanket was objectionable, and in consequence was torn up. Had the brothers objected to green blankets when they were living together before their admission to the asylum? or, if together in the asylum, did one brother copy the other's delusion? Or was the delusion developed, the brothers being in separate sleeping rooms?

These are points upon which we should like to be further informed. The cases are, nevertheless, most carefully reported, and no one can doubt that both brothers were insane at the time the act was committed, and also during the period of their residence in the asylum.—*Rep.*]

The other cases in support of this theory are as follows.

Mdme. X., under the delusion that her solicitor had swindled her, followed him about, and so aspersed his character, that he brought an action against her for defamation. Her relatives having to pay heavy damages, thought it wiser to place her in an asylum, she having, moreover, become violent after losing her cause. After some months, under the promise to give up the pursuit, she was discharged from the asylum. She at once recommenced her attacks upon the solicitor, and other acts of violence were committed. She was then brought to Dr. Brunet for examination.

Opposed by Drs. C. and N., Dr. Brunet declared the lady to be insane. It may be mentioned here, in parenthesis, that one of these gentlemen accused Dr. Brunet of inventing the delusion of his patient to serve his own purposes. We trust that the fact of one brother of our profession accusing another of a deliberate act of falsehood is a form of defence which will never be introduced into this country.—*Rep.*]

The opinion of the other doctors was, nevertheless,

accepted, and Madame X. was again liberated on the condition that she left the country.

[The point of the whole case, however, lies in the fact that the children are said to have inherited the same delusion from the mother. We are unable to perceive how this second illustration points to the theory of the contagion of insanity. If the delusions were really such on the part of the children, they would not alone have constituted insanity. If not real delusions, we can quite imagine children having been so prejudiced in their youth against this notary by the mother, as to believe that he had really swindled them, and in this case the mistakes of judgment of the children would not amount to the pitch of true delusions.—*Rep.*]

The third case is one of a lady aged thirty, who was placed in the asylum at Dijon, as she suffered from delusions of persecution and hallucinations of hearing. She heard voices of people who tormented her, and prevented her gaining her livelihood.

The patient's mother visited her some few weeks after her admission to the asylum, and declared that her daughter had never been insane, that not only had the daughter been really persecuted, but that her enemies had addressed (*sont adressés*) her (the mother) herself for some days, and had wished to bring her to the deepest misery.

The delusions (?) of the mother, communicated to her by the daughter, not being accompanied by hallucinations or unreasonable acts, were not considered sufficient grounds for depriving her of her liberty.

[We should like to know in this third case if there were any grounds for these delusions on the part of the mother. If there were no grounds for them, then decidedly it is the strangest of the three cases illustrating the theory of the contagion of insanity.—*Rep.*]

The paper concludes by the general remarks that in asylums patients can transmit their delusions from one to another, that the study of cerebral physiology easily explains the contagion of insanity, and that at certain epochs, mesmerism, spiritualism, and table-turning have been known to influence a large number of people at the same time.

With regard to this last statement, it may be remarked that such people are not under certificate in an asylum, and that they cannot, therefore, be considered insane in the usual acceptance of the term.

[We have thought it necessary to dwell at some length on this new theory. The point at issue really is not whether insanity generally is communicable, but whether or no delusion is so.

Nobody needs to be told that the insane will imitate one another's monkey tricks, such as making grimaces, extravagance of costume, talking to themselves, and running or jumping about the airing court. We all know how one noisy patient is able to stir a whole ward into a state of turmoil in a very short time. But we must confess to not having yet discovered an instance of one patient distinctly communicating a delusion to another. The very essence of insanity is selfishness, and the insane are usually so much occupied about the consideration of themselves, their supposed injuries, and their delusions, as to find but little time to sympathise with another to such an extent as to catch a delusion from or to impart a delusion to him.

The only point of value about the paper is found

in the first case, where the two brothers, being in (we suppose) separate rooms, developed the same delusion about the green blanket. But this would more illustrate the fact of people similarly constituted (as in the case of twins) being attacked at the same period of life by a non-infectious malady—such as Bright's disease—than that one of them had contracted the same delusion from the other. It is to be hoped that this new theory will not be received until more evidence is produced on the subject of the contagion of insanity.—*Rep.*]

H. SUTHERLAND, M.D.

PONZA ON THE INFLUENCE OF COLOURED LIGHT IN THE TREATMENT OF THE INSANE.—Dr. Ponza, Medical Director of the Asylum at Alexandria, says (*Annales Médico-Psychologiques*, January, 1876) that he happened to read that an English navy captain had succeeded in wonderfully improving the condition of certain animals by putting them constantly under the influence of violet light, and had also developed extraordinary growth in fruit and vegetables by covering them with violet bell-glasses. He then wrote to Father Secchi, director of the astronomical observatory, to ask him if this influence was due to the electro-chemical rays, from whom he obtained certain data, the chief of them being that, 'The walls of the room serving for experiment should be painted of the same colour as the windows, and there should be as many windows as possible, that the light might be received directly at different hours of the day.' Following this advice, he placed in a red tinted room, with red windows, a patient suffering from melancholia, who had long been dull, taciturn, and difficult to feed. Three hours afterwards this patient was visited, and Dr. Ponza found him gay and smiling, and asking for food. A second case was no less instructive. 'J. B., melancholic, who remained all the day with his hands pressed against his mouth to stay the introduction of poisoned air, was placed in the red chamber. Next day he rose, swallowed breakfast with great avidity, and in few days his discharge, as cured, was recommended.'

In a blue-walled chamber Dr. Ponza placed an excited and irritant patient in a strait-waistcoat; in a few hours he was much calmer. Blue light is very active on the optic nerves, as proved by the following incident: One day Dr. Manfredi was conducted into the blue-room after his eyes had been bandaged, and he had been walked several times round the asylum; as soon as he entered the blue room he was aware of it, from the sensation of a strange feeling of oppression.

He then placed an insane patient in a violet chamber; next day the patient asked to be sent home, feeling quite well. He left the asylum, and is well now.

On examining by the spectroscope the curves of light, it is at once seen that the violet rays are those which possess the most intense *electro-chemical rays*, that red light is just as rich in *heat-rays*, whilst blue light is absolutely destitute of calorific, chemical, and electrical rays. Hence the beneficial influence of the latter, since its negativeness is well calculated to soothe the furious agitation of maniacal persons.

The influence of altered light may be with advantage extended to other nervous diseases, chorea, hysteria, epilepsy, puerperal eclampsia, etc.

[There can be no doubt that Dr. Ponza has opened up an interesting subject. It has been long known,

and acted upon, that in treating the insane a *darkened room* is a great calnative. Again, patients who have been supposed chronically insane in gloomy asylums have recovered on being transferred to better-lighted buildings. Hallucinations of vision and temporary colour-blindness are common in all forms of insanity, and it is not difficult to see how, on other than electric caloric or chemical grounds, these phantasies might be met by coloured rooms. The connection of colour with insanity may be again traced in the bits of coloured rags with which many, especially women, adorn themselves, and the choice of *one colour* is by no means uncommon. It is very difficult to get at the real motives of the insane for the refusal of food, but it is quite conceivable that one who refuses drink from the notion that the fluid is blood, may, under the influence of a coloured light, have his subjective state changed by an alteration in the objective conditions. Coloured light is not dissimilar from tones in music, an art too much neglected in the treatment of the insane. The reporter has often been able to infuse life into an apparently demented patient by music of a properly selected character. A notable instance occurs to him in the case of an epileptic who, up to last week, seemed demented and devoid of interest in what was going on around her. The reporter happened to sit down to the piano and play a lively air, when to his surprise she jumped up and danced vigorously, and has been better ever since. The reporter intends to study more accurately the influence of different colours and musical tones in insanity. He has a patient now under treatment, suffering from what he diagnoses as cerebellar disease, involving also the posterior cerebral lobes, before whom he had placed five shawls, coloured violet, black-and-green, white, red, and blue; she preferred the white one; next to that the black-and-green; on no account would she wear the red, blue, or violet. He has another (epileptic) who will only wear red neckties, and it is notorious to alienists how fastidious the epileptics are in choice of colour. Many reflections are opened-up by this question of light, *e.g.* the influence of the Romish religion and of the high church parties by their coloured glass, decorations, and highly coloured music; the exuberance of spirits in Italians and Frenchmen living under a clear white light; the excess of feeling in an audience when the lime-light under coloured aspects is thrown on the stage.—*Rep.*]

T. CLAYE SHAW, M.D.

OBSTETRICS AND GYNÆCOLOGY.

PERUZZI ON A CASE OF OVARIOTOMY DURING SEPTICÆMIC FEVER: RECOVERY.—Dr. D. Peruzzi describes in the *Raccogliore Medico* for September 1875 a case in which he performed ovariectomy in a patient suffering from septicæmic fever, arising from inflammation of a cyst with decomposition of its contents in consequence of puncture.

The cyst was elliptic, having its greater diameter extending from the left central arch to the right groin. Above it, and passing under the xiphoid process, was a hard knotty mass, the dullness over which was continuous with that over the spleen.

On July 21 a puncture was made in the cyst, and gave exit to a dark sticky fluid, like syrup. As this escaped, the hard portion receded more and more from the spleen, until it lay at the level of the um-

bilicus. Nine kilogrammes of very albuminous fluid were removed. On the day on which the puncture was made fever set in, and continued eleven days. It was accompanied by pain, limited to the locality of the cyst. The patient had vomiting and diarrhœa, and wandered in her sleep; her hearing became obtuse, the sclerotic and skin had an icteric tint, and in August once there was a general miliary eruption. It was evident that the case was one of septicæmic fever, the cause of which lay in the ovarian cystic tumour.

Remembering that Dr. Keith had operated in thirteen such cases with only two failures; that Spencer Wells had operated in similar conditions; and finally calling to mind a case in which Wiltshire and Watson had operated successfully on a patient whose life was in danger from hæmorrhage into an ovarian cyst, Dr. Peruzzi performed ovariectomy on August 1. The omentum was adherent to the cyst; four ligatures were applied to it. The pedicle, which was long, large, and flat, was tied. Drainage was practised through the utero-rectal fossa.

Three-fourths of the tumour consisted of a large cyst with very thick walls; the remainder was formed of small cysts with thinner walls. The process of inflammation and decomposition was limited to the large cyst, which had been punctured. Recovery proceeded regularly; the healing of the wounds being nearly complete by the seventeenth day.

A. HENRY, M.D.

TARNIER ON MILK DIET IN THE ALBUMINURIA OF PREGNANT WOMEN, AND ITS INDICATION AS PREVENTIVE TREATMENT OF ECLAMPSIA.—In *Le Progrès Médical*, no. 50 (December 11, 1875) M. Tarnier communicates two cases in which chloral succeeded perfectly in relieving the albuminuria and preventing eclampsia.

The urine contained 55 per cent. of albumen in one case, and under the microscope showed the presence of a large quantity of cells in a state of granular fatty degeneration, hyaline casts and blood corpuscles. Two litres of milk daily were prescribed; the œdema gradually disappeared, and the patient had a normal labour, the child being alive, large and healthy.

The second case was similar, and was delivered naturally at full term of a living healthy child.

Dr. Tarnier suggests that on the first day one litre of milk and two portions of food should be given, on the second day two litres and one portion, on the third day three litres and half a portion, the fourth and following days, four litres, or as much as desired, and no other food or drink. The author remarks that cases of eclampsia may occur without albuminuria, but they are very rare. In cases treated by this method, the albuminuria has either disappeared or diminished rapidly, and eclampsia has never supervened.

BUDIN ON SECTION OF THE UMBILICAL CORD.—In *Le Progrès Médical*, no. 3, January 15, 1876, Dr. Budin concludes an interesting series of articles as to the proper time when ligature of the umbilical cord should be practised. From seventy-five personal observations, he concludes that if ligature of the cord be effected immediately after the birth, we deprive the child of about 92 grammes (over 3 oz.) of blood from the placenta, which is equivalent in the adult to a loss of 1,700 grammes (58 oz.). From this it follows that section should not be performed

until one or two minutes after the complete cessation of the pulsation of the cord. As to the practical question whether it is of any inconvenience to the mother as regards delivery, although certain authors recommend leaving the placenta gorged with blood in order that its separation may be facilitated, M. Budin feels assured that the placenta empty of blood is thrown off more easily, and passes more readily through the contracted cervix, than when it is gorged with blood.

In simple asphyxia of the child it is necessary to allow it to breathe freely and to cry before tying the cord, and to abstain from allowing blood to flow from the cord.

BEIGEL ON THE PATHOLOGY OF DYSMENORRHOEA MEMBRANACEA.—Dr. Beigel (*Archiv für Gynecologie*, Band ix. Heft 1) in an exhaustive article on this subject, arrives at the following conclusions from the results of his examinations.

1. The so-called dysmenorrhœa membranacea occurs in consequence of primary or secondary disease of the uterine mucous membrane—endometritis.

2. The characteristics of this disease consist in a pathological change of the mucous membrane, whereby, in consequence of well-marked cell-proliferation from beneath, the membrane is shed in large shreds or as a continuous sac.

3. The expulsion of this, as a rule, occurs through contraction of the uterus after preceding hæmorrhage, menstrual or otherwise, whereby closure of the os internum by the membrane leads to retention of blood and the production of intense pain.

4. As menstruation plays a secondary part in the development of this affection, and the formation of the membrane is in no way connected with conception or abortion, it seems better to give up the terms 'dysmenorrhœa membranacea,' or 'menstrual decidua,' and adopt the denomination 'endometritis exfoliativa.'

5. The microscopic examination of the membrane furnishes no similar results. In one class of cases we find the normal elements of the mucous membrane merely pathologically increased; in another series the individual elements of this, as the glands or epithelium are lost or in a state of degeneration; in a third class embryonal cellular tissue is formed; and in a fourth epithelium plates or cells, which are very similar to these, alone or in conjunction with the embryonal tissue of the skin-elements of the membrane.

6. In all cases it forms a marked cellular production, constituted of free cells, which form the definite occasion of the loosening of the mucous membrane from its attachment.

7. The pathological changes of the uterine mucous membrane in endometritis exfoliativa appear to be such, that the development of an impregnated ovum in the uterine cavity cannot take place; therefore the patients, as long as they are under the influence of the disease, are sterile.

ARTHUR W. EDIS, M.D.

BREINIG ON RETENTION OF MENSES FROM OCCLUDED OS UTERI.—In the report of the Northampton County Medical Society (*Transactions of the Medical Society of the State of Pennsylvania*, vol. x. part 2), Dr. P. B. Breinig reports a case of retention of menses, for over three years and a half, from occlusion of os uteri, resulting from adhesive in-

flammation produced by severe and protracted labour.

Mrs. O. B., aged twenty-two, in company with her husband and her attending physician, Dr. K., visited him July, 1873, when the following history was elicited. Her health was always good during her single life, and during her pregnancy. In May, 1871, she gave birth to a stillborn child after a severe and protracted labour of nine days, in consequence of which she was very much prostrated, recovering slowly. After due course of time, her menses not returning, medical aid was secured to reproduce them, without benefit. Dr. L. was applied to, and, upon examination with the speculum, found the womb completely closed up. He declined to operate, regarding her case as incurable.

Upon examination the patient was found of medium size, physically well developed, without the appearance of being an invalid. She complained much of distress in the head, vertigo, irritable stomach, pain in the left side and back. The bowels were costive; the appetite variable. There was no discharge per vaginam. Upon further examination by touch and speculum, the womb was found to be enlarged to about thrice the normal size, the orifice entirely obliterated, scarcely a sign being left whereby the os uteri could be discovered.

Consent being had, assisted by Dr. K., a careful dissection was made with Sims' hysterotome, through the os and neck, followed by dilators until a sound could be introduced within the body. Contrary to expectation, but little flow resulted from the operation, and that without much fetor. This operation was followed from time to time by the introduction of sponge and sea-tangle tents, until a free opening through the neck was established. In 1874 she was discharged.

Under date of May 8, 1875, the husband of the patient wrote to Dr. Breinig that his wife had menstruated four times at regular periods, though in a slight degree, after an absence of nearly four years.

MUNSON ON STRAPPING THE BREASTS TO PREVENT AND ARREST LACTATION.—Dr. W. W. Munson of Otisco, remarks (*New York Journal*, November, 1875), that strapping the breasts to prevent lactation seems to be considered a matter of some importance by Dr. Peaslee, as stated in his remarks before the New York Academy of Medicine; he would say that he had used this means four years, in a large number of cases, not only to prevent lactation, but to arrest it after the flow has commenced, where it has been desirable to dry up the milk, after death of the child, or for ulcerated, retracted, or imperfectly developed nipples. A failure has not occurred in a single instance, even in those very large breasts where an abundant flow of milk had been going on for several weeks. He gives details of some very successful cases, and adds: Strapping will be of no use unless it is well done. Let the first strip be put on so as to hold the breast well up by itself alone, whichever direction it is made to take. He usually commences by placing a strip laterally beneath the breast, about half-way between the nipple and lower margin, draws the gland well up, and attaches one end high up on the sternum and the other end high up under the arm. The next strip is placed at right angles to the first, close to the nipple. It is applied to the breast, drawn well up, and the upper end is fastened. It is then brought over the shoulder and is drawn down and firmly fastened. Holes are cut

through the strips that pass over the nipple, so that it may project through. This is to allow the milk which may ooze out for the first few hours to escape, without burrowing beneath the plaster, pushing it off, and making a hot, disagreeable, irritating poultice. Several thicknesses of soft cloth should be placed over the nipple (when pervious), to absorb the milk that escapes. This should be renewed as often as it becomes saturated. A timely application of this plan of strapping he has found almost sure to arrest commencing mammary abscess.

WELLS ON A CASE OF PROLONGED GESTATION. Dr. Frank Wells, Professor of Obstetrics and Diseases of Women and Children in Cleveland Medical College, relates in the *Boston Medical and Surgical Journal* for December the case of Mrs. M., who had sexual intercourse with her husband on August 27, 1874. On the following day her husband was called away on business, which detained him from home until the existence of pregnancy had declared itself by the cessation of the catamenia. She quickened in the early part of January, 1875, and naturally expected to be confined about June 3, for which period she engaged her nurse. Labour did not come on, however, until June 26, nor was it completed until the following day, three hundred and four days from the date of sexual congress. The birth, which was tedious, necessitating the use of the forceps, was characterised by the almost entire absence of liquor amnii. The child, which weighed eight and one half pounds, looked as though it had been in a measure macerated in the amniotic fluid. In November it was healthy and vigorous, and weighed eighteen and a half pounds.

HUGGINS ON A CASE OF PRECOCIOUS DEVELOPMENT IN A CHILD.—Dr. J. Huggins, of Newbern, Alabama, relates the following case in the *Virginian Medical Monthly*, for December. In May 1874, he was called by a negro to visit his little daughter, who was suffering from the general derangements of the system incident to the period of dentition. This condition readily yielded to appropriate treatment. The mother of the child called his attention to a very strange development of the genital organs and mammary glands. On inspection he found the two mammae uncommonly large, being about two and a half inches in diameter, and projecting outwards about an inch. The nipples were correspondingly developed. The genital organs presented a still more precocious development. The labia were unusually large and covered thickly with hair about an inch long. The mons Veneris was also coated with hair, which was not so long as that on the labia.

This precocious development continued about six months, when it arrived at its maximum. The child was then not quite two years old. The two breasts were now about three inches in diameter and otherwise well developed. The hair about the pudenda was longer and more abundant. In a word, the parts were as well developed as they should have been in a girl of fifteen years.

About this time other singular phenomena were presented. About every four weeks the child complained of pains in the lower part of the abdomen, in the region of the right ovary. On examination, Dr. Huggins found considerable hardness and some enlargement in that portion of the abdomen. This hardness continued for several days and then

gradually subsided, but never to its normal condition. Dr. Huggins gave the child bromide of potassium and warm hip-baths. The condition became more aggravated each month until paralysis of the right leg was the result and the child was unable to walk; he then gave iodide of potassium internally and the tincture of iodine externally.

In a few days after commencing this treatment the menses came on, or at least a fluid similar to the menstrual flow ran out of the vagina and continued for about two weeks. In about a month the hardness and paralysis had almost disappeared, and the child was running about in apparent good health. The mammae were reduced to about one-fourth their former size, and since then no material change has taken place in the case. The child is somewhat precocious in intellect as well as physique. In fact the expression of the child's face and the general contour of her features remind one more of a large sized girl than of a little child.

The parents of this child are perfect specimens of the black race, healthy, and have several other children besides the one herein mentioned.

In commenting on this case, Dr. Huggins expresses his belief, which he asserted in a previous report on a similar subject, that all *deformities*, *monstrosities* and anomalies which are met with in the human race, are found more frequently in the black than in the white.

TAYLOR ON HÆMATOCELE OF THE AMNION.—At the meeting of the New York Academy of Medicine on September 16 (*New York Medical Record*, October 9), Dr. Isaac E. Taylor presented a specimen of what he called hæmatocele of the amnion. The placenta was delivered at eight months. The hæmorrhage had taken place between the chorion and amnion, and the amnion could be distended by means of a blow-pipe sufficient to cover a surface six and a half or seven inches in diameter. The specimen was regarded as analogous to one reported by Cazeaux; but in Cazeaux's case the hæmorrhage was between the placenta and chorion. The umbilical cord was attached to the thin delicate amniotic membrane, and when the specimen was removed, the bloody distension of the space between the amnion and chorion was about the size of a large egg.

HAUSSMANN ON THE OCCURRENCE OF CATARRH OF THE FEMALE GENITALS AT VERY EARLY AGES. Dr. Haussmann (*Berliner Klinische Wochenschrift*, January 31) remarks that Kluge thought that all the syphilitic affections of the new-born infant were acquired *in partu* from the mother (see Bärensprung, *Die Hereditäre Syphilis*, Berlin, 1864), an opinion which has not been confirmed by more extended researches. It must, however, be confessed that we do not possess sufficient knowledge of the exact workings of this temporary contact between the mother and child in the act of birth. It is much to be wished that every vaginal catarrh, even those considered harmless, could be cured. Dr. Haussmann has demonstrated for some years past that the liquor amnii bears away with it the greater part of the vaginal mucus, and, further, that during birth the child may get portions of these discharges into its mouth and other natural openings. (See the *Centralblatt für die Medicinischen Wissenschaften*, no. 49, 1869, and *Die Parasiten der Weiblichen Geschlechtsorgane des Menschen und einiger Thiere*, Berlin, 1870.) It is easy to understand, in this way, how

the child's mouth is first affected with thrush (*soor*) of parasitic nature.

Roederer,* Haller,† and Daroz,‡ as well as Carus§ and Bouchut|| have observed a white milky discharge in the vaginae of new-born infants. It does not appear that any of these authors examined it microscopically. Haussmann, in repeating his former observations,¶ found some mucous corpuscles, as well as ordinary pavement-epithelium in the vaginal mucus of a little girl of a week old. In one out of three still-born female children he also found many of these corpuscles in the vagina, whilst no such bodies were found in the normal, healthy, delicate mucus of the uterine canal and other parts of the sexual organs. Donné,** Kölliker and Scanzoni,†† and Robin,‡‡ and many others state that in a normal condition the vaginal mucus only contains pavement-epithelium, or at most a few free nuclei and bacteria. It is clear, therefore, that in the case mentioned there must have been either catarrh of the vagina in the child *in utero*, or that these mucous corpuscles passed from the vagina of the mother to that of the child. In the case of the older child mentioned above it is quite possible that the vulvo-vaginitis was from a sponge contaminated by the mother, as Gaillard Thomas, J. Steiner, §§ and R. Barnes has noticed in other cases. Dr. Haussmann has examined again twenty newly-born female children, and has only found mucous corpuscles at all in four of them; viz. in a 1½, two 3, and one 3½ days' old child. In the remaining sixteen there were none.

Raulin||| thought that leucorrhœa was often inherited, like epilepsy or consumption, and many of the older writers shared this opinion. Without denying it, it would seem unlikely that all the cases should occur so young. On the other hand, the parasitic growths, such as the *oëdium albicans* of Robin, present in the vaginal discharges of the mother, are easily transferred *in partu* to the new-born child; and find their way into the mouth, producing thrush, and into the labia pudendi, thus generating vulvo-vaginitis. He cites Vogel, Gerhardt, R. Maier, Bouchut, and others, in support of this opinion. He is inclined also to blame Sir Charles Locock and Dr. Barnes, the former for saying (in the *Cyclopædia of Practical Medicine*, vol. iii. London, 1834, p. 38): 'In the latter months of pregnancy, leucorrhœa may be looked upon rather as a relief, unless excessive,' and the latter for agreeing with him.

Haussmann says that no leucorrhœa is harmless. The mothers must be looked after during pregnancy; the newly born children should be carefully examined

for any vaginal discharges, which should be carefully treated from the first.

[The original article contains many references to obstetric and other authors, which want of space would not allow to be reproduced here.]

DERMATOLOGY.

WIGGLESWORTH ON IDIOPATHIC MULTIPLE ROUND-CELLED SARCOMA OF THE SKIN.—Dr. E. Wigglesworth, jun., publishes in the *Archives of Dermatology* for January a case of idiopathic multiple medullary round-celled sarcoma of the skin; and adds a retrospect of all recorded similar cases.

A woman, aged forty, noticed in April 1872, a band of small spots, like mosquito-bites, extending across the epigastric and hypochondriac regions. The spots forming this band were faintly pinkish, slightly elevated, hard and discrete. They increased in number, and retained their colour. They were not painful or tender and did not itch.

Dr. Wigglesworth saw her in January 1873, and examined her partially. A complete examination was allowed on February 15. On the external aspect of the upper right arm there was a well-defined firm, convex, bluish-red unlobulated lump, about an inch in diameter at the base, adherent to the skin, slightly elastic, smooth and without fissures or ulceration. No pain was produced even on strong pressure. There were two similar smaller nodules on the upper left arm, one on each side of the lower third of the biceps muscle; on the right forearm, seven, on the left forearm three small, discrete, violet-red firm, slightly prominent infiltrations. The temperature of the spots was normal, and no pulsation or fluctuation existed. The smaller spots upon the forearms shaded off gradually as to colour and consistency into the surrounding skin and were movable with it. The lymphatic vessels and glands were unaffected.

There was a large nodule on the left eyebrow; and forty to fifty additional nodules and spots on the breast, back, inner aspect of the thighs, and nates.

The tumour on the eyebrow was removed on March 8. The wound healed by first intention; but

before long a new nodule formed in the cicatrix. Diarrhœa set in and lasted three days, and was followed by aural catarrh and deafness. Some of the nodules on the legs broke down and ulcerated, and after a few weeks she died from exhaustion. There was no necropsy.

The tumour which was excised 'was spherical, of the size of a large cherry; the surface smooth, covered with a thin translucent layer of epidermis, beneath which were scattered irregularly minute transparent, sago-like granules; balls of epidermis were contained in the dilated hair-follicles, also occasional hæmorrhagic points.'

The cells of the tumour examined fresh were round, relatively uniform in size, considerably larger than a white blood-corpuscle. They contained a nucleus which was large in proportion to the cell. In sections from the hardened specimen, the cells were seen to be imbedded in a reticulated, delicate fibrous stroma, the meshes of which enclosed as a rule single cells. Nuclei in the stroma were not observed. The nodule contained few blood-vessels, but some extravasated blood. The hair-follicles, and the sebaceous and sweat glands, were intact. Large nerve-trunks traversed the diseased tissue. The growth seemed to originate in the papillary layer, extending downwards into the subcutaneous tissue. The specimen was regarded as a round-celled medullary sarcoma.

The case is analogous to those reported by Korte, Köbner, Webber, and Kaposi, but differs in some respects from all of them. It differs from Kaposi's in not having begun on the feet and hands, and in belonging to the group of large-celled sarcomata.

WEISSE ON FOLLICULITIS SEBACEA.—In the *Archives of Dermatology* for January, Dr. F. J. D. Weisse has an article on folliculitis sebacea. This name is suggested as a comprehensive term for the various kinds of acne. The author's own summary of this paper is as follows.

1. In all so-called acne lesions of the sebaceous follicles, a certain degree of inflammation of the follicular wall exists.

2. Folliculitis sebacea would seem to be a much more comprehensive and suggestive generic name for this class of lesions than is the term acne.

3. A deficient ingestion of fats marks the dietary of most patients suffering from folliculitis sebacea.

4. The deficiency of animal oil in the blood of the capillaries of the follicular wall, renders the sebum less fluid; hence stasis of sebum occurs, which pressing on the follicular wall irritates it; inflammation of the same takes place, and hence the several varieties of folliculitis sebacea.

5. The internal therapeutics should be restorative, in furnishing fats to the blood.

6. The external therapeutics should be antiphlogistic by extrusion of follicular contents, douches of hot water, sulphur and camphor lotion, and bismuth and chalk powder.

TAYLOR ON PARTIAL ATROPHY OR PALSY OF THE SKIN.—A case of a rare form of idiopathic localised or partial atrophy of the skin, is published by Dr. R. W. Taylor in the *Archives of Dermatology* for January.

Dr. Taylor's patient was a woman aged forty-five, who had previously enjoyed good health and had borne healthy children. On the extremities and sparsely on the abdomen there were groups of round

and oval patches of skin, of various sizes, from the diameter of two lines to that of half an inch as a limit, having a whitish glossy appearance very much resembling mother of pearl. The surfaces were smooth, but showed the openings of some of the follicular ducts. The patches ended by a sharp well defined margin, and the surrounding integument seemed normal. They were slightly depressed below the level of the skin, and contained no hairs.

Other patches scattered among the white ones were of a light brown colour, somewhat darker than the colour of tinea versicolor. These brown patches were an earlier stage of the white ones, and became white if the epidermis were removed. The former were hyperæsthetic whilst the latter were somewhat anæsthetic. The brown patches grew very slowly; about six months elapsing between the time of the appearance of a small brown spot and its full development as a patch of the largest size.

The woman's appearance at the time was that of a thin, weak and delicate person, whose nutritive processes were performed in a faulty manner, and whose assimilation was imperfect.

Dr. Taylor regards the case as an instance of atrophy of the whole structure of the skin, in the form of round and oval spots, the affection not following previous infiltration, but being atrophic from the beginning. He distinguishes it from the morphœa of Wilson by the absence of infiltration, although he points out that his case closely resembles the morphœa alba atrophica of that author.

G. THIN, M.D.

MARTINEAU ON THE TREATMENT OF PITIRIASIS CAPITIS BY SOLUTION OF CHLORAL.—In a paper read before the Société de Thérapeutique of Paris, reported in the *Bulletin Général de Thérapeutique*, Dr. Martineau advocates the treatment of pityriasis capitis with solutions containing chloral. After remarking on the persistence of pityriasis and its obstinate resistance to the numerous drugs which have been tried against it, Dr. Martineau says, 'If I am not deceiving myself, chloral offers us a means if not certain at least very efficacious for the treatment of this rebellious affection.' In the hands of Dr. Martineau and also of Professor Tardieu, the following solution has given excellent results: water, 500 grammes, hydrate of chloral 25 grammes. This solution should be made lukewarm and applied, in the morning, with a sponge to the diseased parts. The part touched with it must not be wiped. If the pityriasis be recent, a single application will often suffice for its cure; if it be old, it disappears to reappear later on. The solution of chloral always has the effect of causing a disappearance of the rash and the pruritus, so that it is sufficient to continue the lotion in a case of chronic pityriasis until the patient suffers no inconvenience from his disease. If the pityriasis be complicated with any other cutaneous affection, as erythema or prurigo, it is necessary before employing the solution of chloral, to use the following liquid: water 500 grammes, hydrate of chloral 25 grammes, Van Swieten's solution 100 grammes. This solution should be used every morning with a small sponge. When the affection which complicates the pityriasis has disappeared, the chloral solution may be returned to. The application of solution of chloral causes immediate redness of the skin and provokes slight itching, but these inconveniences only last a few minutes.

OPHTHALMOLOGY AND
OTOLOGY.

GALEZOWSKI ON THE IMPLICATION OF THE FACIAL LYMPHATIC GLANDS IN AFFECTIONS OF THE EYES.—M. Galezowski (*Recueil d'Ophthalmologie*, January, 1876), says that the lymphatic vessels of the face are in intimate relation with those of the eyeball and its appendages, and appear to communicate directly with the lymphatic glands in the parotidian region in front of the ear, and also with other glands beneath the lower jaw; and these in their turn are closely connected with numerous glands in the neck.

It has long been recognised that syphilitic sores upon the eyelids may give rise to glandular enlargements in front of the ear and beneath the jaw. This was shown by Ricord and Desmarres. It is, however, to be noted, that amongst English writers Jacob (*Dublin Hospital Reports*, vol. vi.) has expressed his opinion that cancerous affections of the eyelids do not implicate the neighbouring lymphatic glands; according to the experience of Galezowski, however, these glands may become engorged and swollen not only in consequence of syphilitic chancres, but also with phlegmonous inflammation of the eyelids, with certain forms of conjunctivitis, with herpes palpebralis, and occasionally with affections of the lachrymal sac.

With reference to syphilitic affections of the eyelids, it is not yet clearly shown that any but primary chancres will involve the neighbouring glands, although Galezowski has seen one or two cases in which their swelling has been noticed with secondary affections of the conjunctiva. The case in which glandular enlargement was associated with a lachrymal tumour, and which is recorded at length in the paper, was a remarkable one. It was that of a young girl, in whom an enlargement of all the glands of the face and neck followed inflammation of both the lachrymal sacs; in this instance the glands of the chin, as well as the masseteric, buccal, and submaxillary glands were involved, although it is probable that in this instance some special diathesis was at work to produce this very extraordinary continuation of symptoms.

It is, according to the author's experience, abundantly clear that the enlargement of the facial glands may arise under various conditions, quite independently of syphilitic affections.

GALEZOWSKI ON THE CURABILITY OF DETACHMENT OF THE RETINA.—M. Galezowski's experience (*Recueil d'Ophthalmologie*, January, 1876) has shown him that in a certain proportion of cases of detachment, a cure may be effected by surgical treatment. Of 211 cases of detachment which he has tabulated, he finds but 13 instances in which it has occurred in eyes that were not myopic, so that he assumes that a myopic conformation of the eye is almost indispensable for its production. He con-

siders also that he has established the fact that the detachment is always due to subretinal effusion which is brought about by a serous cyclitis; in support of this view, he adduces the frequent occurrence of iritis at the outset of the disease. The subsequent formation of cataract, too, is the result of an affection of the choroid and not of the retina. According to the researches of Poncet (*Société de Biologie*, 1873) the posterior portion of the choroid presents very little trace of parenchymatous inflammation in serous choroiditis, while the ciliary zone almost invariably does so to a considerable extent; and in consequence of this the detachment in these cases commences at the ora serrata, and may extend to the neighbourhood of the papilla. Dr. Galezowski considers that the detachment which is met with in cases of glaucoma has its origin in the same way; and his own practice has shown him that an iridectomy has proved sufficient to arrest the progress of the detachment, and to bring about a great improvement in vision in a considerable number of instances. An analysis of the author's table of cases shows that detachment is almost confined to eyes which are myopic; that it is twice as frequent in the eyes of men than of women; that it is very often complicated by iritis or cataract; and that it may be brought about in consequence of injury, by syphilis, or by rheumatism.

At the very commencement of the affection and in young subjects, much benefit may be obtained by antiphlogistic treatment, but it will be necessary that the patient should remain for several weeks in a horizontal position, and that he should certainly abstain from using the eyes. In this way Dr. Galezowski considers that he has cured several such cases, and he formulates the results of his experience in his concluding sentences.

1. Detachment of the retina admits of cure.
2. In recent cases, and especially in young subjects, antiphlogistic treatment combined with absolute rest will sometimes bring about a complete recovery.
3. In detachments of long standing an iridectomy is capable of arresting any further progress, but it will not prevent the occurrence of cataract.
4. In cases brought about by syphilis, mercurial treatment by inunction will effect a cure.
5. In an eye in which a detachment has receded, one generally finds a white striated appearance where the retina has been disturbed, with more or less evidence of atrophy of the subjacent choroid.

BOWATER J. VERNON.

THEOBALD ON TINNITUS AURIUM.—Dr. Theobald, in the Transactions of the Medical and Chirurgical Faculty of Maryland (*Chicago Medical Journal and Examiner*, November, 1875), gives his opinion of the cause of imaginary sounds in the ear. He thinks, in the first place, that the tinnitus is invariably due to an excitation of the terminal elements (not the trunk) of the auditory nerve; and after a careful consideration of the facts which seemed to have any bearing on the subject, he has been led to the conclusion that in almost all cases, tinnitus aurium, whether associated with aural affections, cerebral diseases, or constitutional disorders, is to be attributed to the existence of vibrations excited in the walls of the blood-vessels of the labyrinth, by the friction attending the circulation of the blood, which are capable of imparting to the labyrinthine fluid, and thence to the terminal fibres of the audi-

tory nerve, impulses similar in character to those which are produced by the vibrations of the stapes, and hence, like them, capable of giving rise to the sensations of sound.

The vibrations of these vessels can produce a sensible impression on the auditory nerve in two ways. First, the intensity of the vibrations may be increased. Second, the vibrations remaining unaltered, their effect upon the nerve may be magnified by reflection and contraction, or by resonance. The first condition will obtain whenever the natural and easy flow of blood is perturbed, as in hyperæmia and anæmia of the labyrinthine vessels, by partial compression of the vessels by inflammation or other causes; especially by an incursion of the stapes by which the tension of the labyrinthine fluid is increased. By the second mode—resonance or reflection—the tinnitus is produced which accompanies the affections of the middle and external ear. The conducting apparatus of the ear is defective; therefore, sonorous undulations from without fail to reach the auditory nerve, and on the other hand sonorous vibrations arising in the ear are not allowed to escape; they are reflected, concentrated, and their sound magnified.

GUYE ON THE DANGERS OF BREATHING BY THE MOUTH.—At the international medical congress in Brussels in 1875, Dr. Guye read a paper in the otological section (*Archiv für Ohrenheilkunde*, February 4, 1876), on the dangers to the ear of breathing by the mouth. According to the author, the habit of breathing by the mouth, frequent among deaf people, is a very pernicious one, and he is much surprised at the almost entire absence of papers on the subject. Respiration by the mouth, which is easier than respiration by the nose, cannot with safety be substituted for it, as nasal respiration answers certain requirements which oral breathing cannot supply. The function of the nose in respiration is threefold. 1. The olfactory sense secures it against the entrance of impure air. 2. The moisture of the nasal passages gives a certain degree of aqueous saturation to the inspired air, the contact of which is thus rendered less irritating to the mucous membrane of the throat and larynx. 3. The inequalities of the organ retain solid particles suspended in the air, which is proved by the quantity of dust sometimes found accumulated in the nostrils.

These advantages are absent in respiration by the mouth. The contact of dry air soon produces circulatory troubles in the pharyngeal region, and even an habitual catarrh, susceptible of easy transmission by continuity to the Eustachian tube and cavity of the tympanum. Granular or adenoid pharyngitis often has this origin. In support of his opinions the author adduced the authority of Dr. Paul Niemeyer of Magdeburg, who considered that the attacks of pseudo-croup, to which children are often subject during the first hours of the night, had their origin in dryness of the glottis produced by oral respiration. To obviate this inconvenience the principal object was to restore the nose to its proper condition, and for this purpose it is important to oblige the patient to breathe by the nose. As we cannot rely on the will of the individual, especially if a child, Dr. Guye proposes to produce occlusion of the mouth by a little instrument of the shape of the respirator, but differing from it in this essential particular, that it is entirely impermeable to air. This 'contra-respirator,' as the author calls it, constitutes a simple and easily

applied means which has produced excellent results in Holland. Dr. Guye cited cases of catarrhal deafness which he had completely cured by this means alone, without any other treatment. [The danger to the Eustachian tube of breathing by the mouth was recognised by Mr. Toynbee, who, in his work on the Diseases of the Ear, in speaking of the treatment of obstruction of the faucial orifice of the Eustachian tube by thickened mucous membrane, advised the patient to practice nasal respiration.—*Rep.*]

BURCKHARD-MÉRIAN ON THE PROPHYLAXIS AND TREATMENT OF AURAL DISEASES.—Dr. Danjoy, in the *Annales de Maladies de l'Oreille et du Larynx*, for December 31, 1875, gives an abstract of a lecture on the above subject, delivered by Dr. Burckhard-Mérian at the Medical Society of Bâle, which was reported in the *Correspondenz-Blatt für Schweizer Aerzte* for September and October, 1875.

The author commences by showing what are the most common causes of diseases of the ears and by what means they may be best avoided. He points out in the first place awkward attempts at cleanliness made with sharp instruments—hair-pins, steel pens, pencils, matches, etc. These instruments may not only wound the auditory canal, but they may even lacerate the tympanum, either by direct contact or indirectly, if they touch a plug of hardened wax. He proposes in their place a small sponge fixed at the end of a handle, this sponge, as long as the auditory canal, sufficing perfectly for cleansing it. Injections are equally pernicious in numbers of instances, either because they are used too cold or because they are made too forcibly. The author thinks also that some discharges are maintained by too frequent injections; he prefers in such cases to make insufflations of astringent powders. Fumigation by vapours, and the dropping in of oil, are also far from being inoffensive. In certain cases there has been found at the bottom of the meatus and near the tympanum a deposit of oil which, remaining at a temperature of about 37° (98° F.) underwent a change, and became the seat of aspergillous vegetation, thus affording a new cause of irritation for the neighbouring parts. Instillations of irritant liquids, often made on account of toothache or neuralgia, may similarly cause external otitis; we need only mention ether, chloroform, alcohol, etc.

Instead of poultices, which often favour the production of diffuse inflammation, the author prefers the introduction of some drops of tincture of opium on cotton-wool, the application of one or two leeches in front of the ear, or cold, which has never caused accident when the necessary precaution has been taken of preserving the auditory canal with cotton-wool.

Cold, which has just been mentioned as an advantageous therapeutic agent, may be the cause of diseases of the ear, the author instancing in the first line among the external causes of these affections, exposure to a current of air as one of the most frequent. When the ear has been cleared from a plug of wax, it should be protected by a little cotton-wool against the external air, for fear of cold. Patients should also carefully guard themselves against cold when they take sea-baths, river-baths, or when they are following hydropathic treatment. The author mentions finally discharges of fire-arms, startling noises, boxes on the ear, as frequent causes of otitis, and concludes the paper by some therapeutic considerations. W. DOUGLAS HEMMING.

WEBER-LIEL ON THE MEMBRANA TYMPANI SECUNDARIA.—In the January number of the *Monatsschrift für Ohrenheilkunde*, Dr. Weber-Liel, of Berlin, records the following experiments which he has made on the membrane of the fenestra rotunda.

1. Having prepared a dissection in the manner described in a former paper, he placed on the external meatus an India-rubber tube, and breathed gently through it. Watching the secondary tympanic membrane under an enlargement of from 15 to 40 linear, he found that it moved outwards and inwards with the inspiratory and expiratory acts, and it appeared to do so relatively to a greater extent than the simultaneously moving drum.

2. Closing the tympanic cavity by means of a covering glass, he, through a catheter in the Eustachian tube, condensed the intratympanic air by driving in air from an India-rubber bag. Under this pressure the secondary membrane was very slightly pressed inwards, while the primary membrane was pressed strongly outwards. On rarefying the air in the cavity by suction, the secondary membrane bulged, especially in the under portion, in a direction outwards and backwards, and on condensing the air, it moved into its former position.

3. The same was observed when the same preparation was used with the inco-stapedial joint loosened, or when the labyrinth was opened.

4. When the investigator fastened to the round membrane a small feather taken from the wing of a canary, and caused a condensation of air with an open tympanic cavity, and an inco-stapedial joint intact, a very short motion of the feather was observed; but when the air in the meatus was rarefied, the feather was seen to move to a greater extent in a direction outwards and backwards. When the feather was dusted with fine starch-granules and one sung or fied into the meatus through an India-rubber tubing in connection therewith, the excursions of the light reflex from the starch-granules were seen to have the same direction.

5. On opening into a preparation of the labyrinth, and cementing a thin tubule into the scala tympani, he found that suction at the other end of the tubule caused only a slight shaking of the membrane, and that it was more tightly expanded, but did not move inwards. But when the air in the scala tympani was condensed, the membrane was widely pressed outwards, especially at certain points.

6. In three fresh preparations the superior semi-circular canal was opened, and a fine glass tubule inserted, and cemented thereto, care being taken that no labyrinthine fluid escaped. This glass tubule was so placed in connection with an India-rubber tube, that motion on the end of the tubing did not break the tubule. The secondary membrane was now placed where it could be examined microscopically; and on suction being made through the tubing the membrane moved towards the labyrinth.

From these observations it follows that the membrane of the fenestra rotunda is capable of greater excursion than has been supposed; further, that it follows easily and quickly all changes of pressure, both from the fenestra ovalis and the tympanic cavity. Towards the labyrinth it moves, but very slightly, from its position of rest, on account of the counter-pressure of the labyrinthine fluid. Towards the tympanic cavity the membrane is capable of great excursion to a certain point.

BUCK ON MEDICATED EUSTACHIAN BOUGIES.—In the *Transactions of the American Otological Society* for 1875, Dr. Alfred H. Buck advises the use of medicated Eustachian bougies as the best means of bringing nitrate of silver into close proximity with the middle sac when it is desirable to do so. He uses the old whalebone, or catgut bougie, not exceeding one millimetre in thickness. Roughening the sides of the bougie at one end, he twists cotton-wool round it, so that a bulb of wool is formed of $2\frac{1}{2}$ millimetres in diameter. This serves not only as a soft covering for the point of the bougie, but also as a sponge for holding a sufficient quantity of the remedy to be used. The cotton-bulb, having been saturated with the solution to be employed, is passed into the Eustachian tube about five-eighths of an inch beyond the end of the conducting catheter, 'or fairly to the membranous or osseous portion of the tube. The instrument should remain there for a few seconds, or perhaps a minute, and then be withdrawn.' He uses nitrate of silver in preference to any other remedy, and has used it in strengths varying from the solid salt to a solution of twenty grains to the ounce of water, 'without setting up any unpleasant reaction.'

REPORTS OF FOREIGN SOCIETIES.

MEDICAL SOCIETY OF BERLIN.

November 17, 1875. *Primary Infective Osteomyelitis*.—Dr. L. Friedmann read a paper on this subject, and related a case. He remarked that the terms primary infectious osteomyelitis and periostitis were introduced by Lücke to designate a disease which had received various names from different authors. About twenty-two years ago, Chassaignac first discovered the disease, and called it 'essential osteomyelitis,' 'typhus of the bones,' 'typhus of the limbs,' 'spontaneous diffuse osteomyelitis.' Klose speaks of meningo-osteomyelitis; Gosselin describes it as 'epiphysal osteomyelitis'; Wernher as 'epiphysal osteochondritis'; Waldeyer as 'periostitis'; Roser as 'pseudo-rheumatic inflammation of the bones and joints in youth'; and R. Volkmann describes partly it as 'spontaneous osteomyelitis,' partly as 'malignant periostitis.' Finally, Bardeleben, in the latest edition of his work, treats of it under the heading 'inflammation of the bones before the completion of

growth.' Lücke points out its identity with an infective disease. In its symptoms and course it bears the closest resemblance to pyæmia; and those authors who speak of spontaneous pyæmia are not in error, if it be allowed that in this case there is a disease which arises and runs its course like an infective disease, but which has its origin not in the intestinal canal nor from an injury, but in the hitherto intact marrow or periosteum. The disease is special to the period of life when growth is not completed. The geographical range of the disease is said to be limited; and but few cases have been observed in Berlin. Dr. Friedmann's patient was a boy aged eleven, previously healthy, who, some weeks before he first came under observation, fell while engaged in gymnastic exercises, and complained of pain in his leg. He was, however, still able to go to school. On October 11, he complained suddenly of pain in the left thigh, especially about the knee, and went to bed. On October 12 his medical attendant diagnosed incipient coxitis, and ordered rest, leeches on the hip-joint, and the application of a bladder of ice. On the 15th, when Dr. Friedmann first saw him, the temperature was (to the touch) normal, and the pain was somewhat abated. The left leg was somewhat bent, but was neither abducted and rotated outwards as in the initial stage of coxitis, nor adducted and rotated inwards, as when the disease is more advanced. Passive movements at the hip-joint could be made without pain and without moving the pelvis. There was pain and slight swelling in the left groin. On the next day, without rigor or any other premonitory symptom, very high continued fever set in. The skin was dry and burning hot; temperature 104° Fahr.; tongue rough and fissured; pulse 130. Passive movements of the hip-joint and pressure over the shaft of the femur produced severe pain. There were also bilateral parotitis and swelling of the left submaxillary gland. The spleen was not enlarged, nor were there any indications of disease in the intestinal canal. On the 20th, the skin was pale, earthy, but not icteric. The patient had constipation. In the upper third of the thigh, and also over each knee, was a slight oedematous swelling; over the right patella was a limited redness, beneath which fluctuation could be indistinctly felt. The parotitis had considerably increased. The left thigh was still tender, and it was believed that there was malignant periostitis. On the 22nd, the left parotid gland had decreased in size, and the swelling of the left thigh and knee had almost disappeared. On the 23rd, small abscesses, varying in size from a linseed to a pea, appeared under the skin of the abdomen on the left side. The soft parts of the left thigh presented nothing abnormal, nor did the limb appear larger than the right. Sometimes, however, emphysematous cracking could be detected with the finger, especially near the knee-joint. The patient lay comatose, but answered and put out his tongue when loudly spoken to; he had the *facies Hippocratica*. On the evening of the same day he died. At the necropsy, the left femur, which was shown, presented the following appearances, revealed on longitudinal section. Nearly the whole of the marrow was in a state of purulent osteomyelitis, a few free points only existing in the centre of the great medullary cavity. There was diffuse purulent infiltration from the epiphysal lines through the whole of the spongy portion, reaching nearly to the middle of the bone; there were also a few small disseminated purulent collections in the epiphyses.

Nearly all authors have called attention to the frequency of separation of the epiphyses in primary infective osteomyelitis; and it was interesting that both at the upper and lower parts of the femur cavities were found in the epiphysal cartilages, indicating the commencement of separation. Nothing abnormal was found in the cortical substance of the femur. The periosteum was separated from the bone by purulent collections for a rather considerable extent close above the knee and below the hip. The left knee-joint was sound; the hip-joint contained pus, but the articular cartilages, the round ligament, the capsule, and the cartilage of the acetabulum, were unaffected. No bacteria or any similar organisms were found in the pus of the marrow, or in the subperiosteal abscesses. There was a subperiosteal purulent collection at the upper part of the right tibia; it had opened into the knee-joint, but without destroying the cartilages or ligaments. The abscesses in the abdominal wall contained an abundance of pus. There was a moderate amount of ichorous exudation on the pleura and pericardium; and the muscular substance of the heart contained fibrino-purulent deposits. There was a fibrinous deposit in the left heart. There were no fatty embola or abscesses in the lungs: but the upper lobes were in a state of commencing hypostatic pneumonia, and the middle and lower lobes presented grey hepatisation. There was some sero-purulent fluid on the peritoneal cavity. The liver, spleen, and kidneys were normal. The examination of the head, or of the parotid glands, was allowed. The veins contained thick tarry blood, like that of septicæmia. Speaking of the relation of the disease to typhus (enteric) fever and acute articular rheumatism, Dr. Friedmann said that the diagnosis from enteric fever was very easy, especially in consequence of the early appearance of the local symptoms and the absence of enlargement of the spleen. He had, moreover, had several cases of typhus in the neighbourhood of the house where the patient lived, and, from the similarity of the symptoms, was led to believe that the origin of the disease in his case of osteomyelitis and in the cases of enteric fever was the same. The diagnosis from polyarthritis rheumatica in its most severe form—as described by Kussmaul and Volkmann—lay in the fact that pressure on the femur in an early stage of the disease produced pain at a part which was found to be the seat of purulent deposit, and in the small number of parts affected, as well as in the circumstance that primary infective osteomyelitis is much more frequent in youth than the severer forms of rheumatic polyarthritis. That the osteomyelitis was the primary disease, and not the periostitis, was shown by the fact that there was only a slight swelling of the soft parts of the thigh; as well as by the amount of destruction of the marrow and the commencing separation of the epiphyses. He called special attention to the absence of rigors at the outset of the disease, which Lücke had also observed in eight out of twenty-four cases.

December 1. *Primary Infective Osteomyelitis*.—In connection with Dr. Friedmann's paper, Dr. Senator described a case of primary infective osteomyelitis. During life, the patient, a girl about fifteen years of age, presented symptoms which were regarded as indicating enteric fever; there was a very moderate affection of the thigh, which was attributed to a fall from her bed; and the true nature of the disease was only discovered by the necropsy. He thought that it was a too one-sided view to regard the general

affection as secondary to the osteomyelitis; there might be cases in which the affection of the marrow was secondary, as had been shown by Ponfick; e.g. the disease of the marrow in relapsing fever. Murchison had said that he met with necrosis in several cases of enteric fever in young persons: perhaps some of these were cases of osteomyelitis. Dr. P. Güterbock had seen six cases of the disease; two had also occurred in his father's practice, and one in that of Dr. Wilms. He believed that it was more common than was generally supposed, and that it was not limited to young subjects. Acute osteomyelitis might occur in the following circumstances:—1. When there was a specific infection; 2. When there was destruction of the integrity of the bone closing in the medullary canal; 3. When some proximate cause (a wound or cold) was present. The course and result of osteomyelitis following amputation was by no means essentially different from the affection described by Dr. Friedmann. The former occurred under various conditions, but was generally complicated with pyæmia. In a case to which he briefly referred, there was a non-febrile interval of two days between the appearance of the disease in the bone and an attack of pyæmia, of which the patient died twelve days afterwards. Between such cases and that related by Dr. Friedmann there were many transitional ones, in which the traumatic cause was more apparent. Some of his own cases were examples; also one related by Roux, in which the disease was set up by a bullet that did not completely penetrate the bone; and also one of Cæsar Hawkins, in which the scraping out of an abscess of the tibia was followed by local sloughing, pyæmia, and death; metastatic abscesses being found in the lungs and septic inflammation in the pleura and peritoneum. The tibia was much inflamed, and there were purulent deposits in the spongy substance and several ecchymoses. The way in which infection reached the bone was not the same in all cases. In patients who had a bullet in the medullary canal and suffered comparatively little trouble from it until osteomyelitis broke out with a sudden rigour, there was, so to speak, an already existing affection, which localised itself as osteomyelitis in the weakest part. Just so, in the osteomyelitis of young subjects, the disease of the bone, as Volkmann had shown, stood in the same relation to general infection as a suppurating subcutaneous fracture to pyæmia. Diseases of bones resembling the so-called spontaneous osteomyelitis might occur in the course of glanders, as was shown by a preparation of a clavicle in the museum of St. Bartholomew's Hospital in London. The disease affected all parts of the bone; but it was advisable to retain the name osteomyelitis, both on account of the importance of the condition of the medullary canal, and to avoid increasing the already superabundant nomenclature of bone-diseases. It was incorrect to assume that the medulla was not implicated because drops of fat did not escape spontaneously or on incision.—Dr. Goldammer had observed, in conjunction with Dr. Güterbock, two cases of osteomyelitis of the femur and tibia, and had seen three others in which the humerus, femur, and tibia were affected. Of the patients, three were aged from thirteen to sixteen, and two were twenty years of age. The case of osteomyelitis of the humerus had been diagnosed as one of articular rheumatism. After the patient's death, there was found to be osteomyelitis, with separation of the upper epiphysis and embolic deposits

in the lungs. Two patients with osteomyelitis of femur were admitted into hospital as cases of typhus; one of them died, the other left the hospital after some time with a rather considerable enlargement of the femur. Of the two cases of osteomyelitis of the tibia, one died, and numerous embolic deposits were found in the lungs; the other recovered, after amputation of the thigh, and in his case the knee-joint and medullary cavity of the tibia were found filled with pus.—Dr. Julius Wolff had endeavoured, but as yet without success, to gain accurate information as to the frequency of pernicious primary osteomyelitis in Berlin. It was certain, however, that the disease occurred there more frequently than had been generally recognised. He had been told by Virchow that primary osteomyelitis was rather frequently met with at the necropsies in the Charité Hospital. It must be remembered that in many cases the disease was treated as typhoid or as acute articular rheumatism. On the other hand, it would be an error to regard the disease as one of every day occurrence, and generally known. For several years Orth had not met with a case; and of the twenty cases recorded by Bardeleben, most occurred in Greifswald. The disease appeared to occur more frequently in some parts of Berlin than in others, especially in the 'Bethaniengegend.' He (Dr. Wolff) considered that traumatic osteomyelitis was altogether distinct from the primary form of the disease. Traumatic osteomyelitis had its origin in an open suppurating focus, to which, as in pyæmia, secondary deposits were associated. Primary osteomyelitis ran its course like spontaneous pyæmia, and the etiological condition might be a trifling injury, or no injury at all but a chill. Although the symptoms of primary osteomyelitis resembled those of enteric fever, there was nothing in common between them, as osteomyelitic disease and intestinal ulcers were not met with together.—Dr. E. Küster differed from the opinion of Dr. Wolff as to the identity of osteomyelitis with pyæmia. Osteomyelitis was in all cases a disease *sui generis*, which might, but did not necessarily, lead to pyæmia. He thought that there was no essential difference between the traumatic and the primary forms of the disease, if the absence of a wound in the latter case were put aside. The infective character of the disease was not clearly proved, and he preferred the name primary or spontaneous osteomyelitis, which did not prejudice the question. The course of the disease varied much in intensity. But even the most severe and rapid cases had nothing so very extraordinary in them, when it was remembered that absorption of decomposed matter took place very readily in bone, and that feeble anæmic badly nourished subjects, as those in most of the cases related appeared to be, were liable to very extensive disturbances from causes which would scarcely affect the healthy. He thought that the disease in question must be regarded as being at first a purely local affection, which, under unfavourable conditions of the diseased part and of the individual, easily led to secondary disorders, to infection of the whole body.—Dr. Retslag had seen a case of osteomyelitis in a patient aged nineteen, who recovered in the Charité Hospital after amputation of the thigh.—Dr. D. Löwenstein had seen a case of osteomyelitis which had been mistaken for enteric fever, but in which the great painfulness of the leg led Dr. Bardeleben to diagnose the true character of the disease. The tibia was the bone affected, and the patient recovered after his thigh

had been amputated.—Dr. Wolff said that Dr. Küster had misunderstood him as to the identity of the character of the disease in osteomyelitis and pyæmia. What he meant was, that there was a striking resemblance between them in the occurrence, first of primary, and then of secondary, purulent deposits.—Dr. Ewald said that in a number of cases of enteric fever there was very severe pain in the ankle-joint, which generally passed off, but might lead to error. In not a few cases it was impossible to establish the differential diagnosis between osteomyelitis and enteric fever.—Dr. Senator had to add to the report of his case, that no micrococci were found in the pus, and that the neighbouring joints were quite free from lesion. He had not desired to identify or to confound enteric fever and osteomyelitis; but the latter might arise in the course of diseases such as enteric fever, as it was known to have done in glanders.—After some further remarks from Drs. Güterbock, Friedmann, Goldammer, and Wolff, the discussion was closed; the president, Dr. Henoch, remarking that he regarded the opinion of Dr. Küster, that osteomyelitis was a purely local affection, as the most correct one.

December 8. *Effect of Injections into the Ear on the Pressure in the Labyrinth*.—Dr. Weber-Liel made a demonstration on a preparation of an ear, to show with what ease variations of pressure on the labyrinth might be produced by simple injection into the external ear. The preparation was taken from a man on whom, during life, giddiness and fainting were produced by injecting the ear with water for the purpose of dislodging an accumulation of cerumen, after the removal of which a loss of substance was observed at the upper part of the membrana tympani. The symptoms were regarded as reflex, from irritation of the auricular branch of the vagus nerve. Experiment, however, showed that they were dependent on the variations of pressure within the labyrinth produced by the injection.

Salicylic Acid and Salicylate of Soda.—Dr. Ewald made a report on the experiments which he had made in Dr. Frerich's wards with salicylic acid and salicylate of soda. He found that the latter was to be preferred as being more reliable in action, and not producing the uncomfortable feelings which followed a dose of salicylic acid. The salicylate was given either in single doses of 5 or 2½ grammes, or in daily quantities of 5 grammes (77 grains), divided into doses taken every two hours. It was only with the first form of administration that striking results were obtained, the temperature falling as much as 72° Fahr. in from five to ten hours. Of one hundred cases of enteric fever, during the height of the disease, the afternoon temperature in eighty was reduced below that of the morning by a single dose of the salicylate of soda given at noon. Among the symptoms produced by the salicylate the most important was profuse perspiration, which set in five or ten minutes after the administration of the medicine. There did not appear, however, to be any direct connection between the sweating and the lowering of the temperature. Nausea was produced in a few cases only, and was in these prevented by adding three to five drops of chloroform to the medicine just before it was taken. The appetite remained good in all the cases; there was no pain in the stomach, and the peristaltic action of the intestines was increased—at least, the stools became more copious. The action on the pulse and respiration was almost *nil*. Symptoms of intoxication,

such as noises in the ears, faintness, and slight hallucinations, were shown in two cases only, and soon passed off. While he regarded salicylate of soda as at least equal to all other antipyretics, he warned against its incautious administration to weak cachectic individuals, in whom the great and rapid lowering of temperature might easily lead to dangerous collapse. He had found it useful also in other acute and chronic febrile disease; but in intermittent fevers salicylic acid was without effect.—Dr. Goldammer confirmed Dr. Ewald's observations as to the effect of salicylate of soda in lowering the temperature. He had not, however, been as yet able to convince himself that the course of cases of fever was changed even if the temperature were lowered. He had seen cases apparently mild at first end fatally, although a favourable influence had been produced in the temperature by the use of salicylate of soda.—Dr. B. Fränkel regarded the substitution of salicylate of soda for salicylic acid as important, since, in two cases of mild diphtheritic inflammation of the fauces treated with salicylic acid gargle (1 in 100 of glycerine), he had seen produced inflammatory swelling of the whole of the mucous membrane of the pharynx.

December 15.—*Infant Mortality in Berlin*.—Dr. Baginski made a communication on this subject. In 1875, from January to October 1, 24,388 persons died in Berlin, of whom 11,700 were children under one year old, and 3,897 were from one to five years. Infantile cholera and diarrhoea caused death in 5,267 children, of whom 4,692 were under one year. The months of greatest mortality were June (1,383), July (1,766), and August (1,088). He regarded this mortality as dependent on the simultaneous action of a number of very important meteorological phenomena, in the falling of the ground-water, the increase of temperature of the air and ground, the diminution of atmospheric moisture, and the absence of rainfall. He cited also Schwabe's remarks on the danger of cellar-dwellings, and described some experiments which he had made with human milk and with children's food. Having placed human milk, cows' milk, Swiss milk, and Nestlé's and Tempe's foods, at a temperature of 37° Cent. (98.6° Fahr.), he found that human milk resisted decomposition longest; then came cows' milk and Swiss milk, and lastly the artificial foods. The latter appeared to keep better when prepared with water to which cows' milk had been added. He insisted on the importance of healthy dwellings and good milk.

ACADEMY OF MEDICINE IN PARIS.

January 25, 1876. *Glanders Leucocythæmia*.—M. Colin, continuing his description of his investigations on the blood in glanders, began by endeavouring to determine what should be understood by the term virulence. He contested M. Chauveau's investigations into the virus of vaccine and glanders, and condemned the diffusion method, by which two liquids of different density were superposed in the hope that one would by diffusion yield a portion of its principles to the other. Vaccine, an albuminous liquid, could scarcely yield anything to the water above it. The method of washing, applied to glanders, was scarcely more conclusive; the first waters of the washing transmitted the disease, the last were innocuous, because they only contained changed elements. M. Colin was of opinion that

'the virulence of animal liquids is independent of their formed elements, leucocytes, globulines, red corpuscles, epithelial cells, and of all kinds whatsoever of nuclei or granules. It belongs to the liquid in mass; to the whole substances. To this conclusion he was led by his researches on *charbon*, septicæmia, vaccine, and glands. Returning to leucocytosis, M. Colin treated successively the following questions. Are there several forms of leucocytosis? What is the starting-point of these conditions? Is glanderous leucocytosis a special leucocytosis? He protested against the supremacy of micrographic theories in the domain of pathological facts. Since histologists have pointed out elements analogous to those of the lymphatic glands in the spleen, thymus, intestinal walls, etc., splenic, intestinal, and other forms of leucocythæmia have been created. And yet the physiological function of the spleen itself is as yet unknown. In the majority of cases of leucocythæmia the spleen is swollen, but is that an effect or a cause? It is not very probable that it should be a cause; for, 1. the veins of the liver do not contain more white corpuscles than the other branches of the portal vein; 2. the lymphatics springing from the spleen are not richer in leucocytes than the rest of the system; 3. extirpation of the spleen does not change the proportion between the red and white corpuscles. Besides this, the obstruction of an organ, far from augmenting, diminishes the secretion of them; as in the kidney, liver, etc. As to the glandular system of the intestine, it would result from M. Colin's experiments that they were secreting and not lymphatic organs; besides which, their number would not allow the production of leucocytosis. He equally denied the leucocytosis arising from a process effected by the marrow of the bones; the modifications undergone by the bony marrow in emaciated animals constituted a general fact in connexion with marasmus, which had nothing to do with leucocytosis. It was with other and better materials that the history of leucocytosis must be constructed.

February 1. M. Colin continued the reading of his memoir, and sought to establish that all the leukæmic conditions were of lymphatic origin, were of the same nature, and resulted from the temporary or prolonged preponderance of the formation over the destruction of leucocytes; that the symptoms of these leukæmic conditions resulted from disturbances produced in the circulation, hæmatisis, and nutrition, by leucocytes in excess; that in virulent diseases leucocytes were rather effects than a cause of the virulence; finally that, in contagious maladies, they had no specific character. In support of these propositions he cited experiments. He had produced fistulæ of the thoracic duct in cows and bulls, and had collected in four and twenty hours, from 15 to 95 kilogrammes of lymph; this enormous mass, rich in leucocytes, would suffice amply to bring on a leucocytosis, if leucocytes thus thrown into the blood were stable and not transitory elements. In opposition to the opinion of the Germans, leucocytes were found in the last lymphatic networks when the lymph had not passed through any lymphatic gland. Leucocytes were essentially unstable mobile elements, undergoing rapid modifications. While leucocytes were very active, emitting numerous prolongations in lymph, they were less so in blood, and these characters were still less in other media. In conclusion, M. Colin decided on the lymphatic origin of all the leukæmic conditions. All leucocytoses developed themselves

rapidly on account of the great mass of lymph elaborated and poured into the blood by the lymphatic organs. They did not necessarily require hypertrophy of the lymphatic glands. There was nothing to prove the splenic, intestinal, etc. origin of certain leucocytoses. Between the physiological and pathological leucocytoses, there was no difference of kind, but simply of degree and duration. The leucocytoses of the poison-diseases had no special characteristic; the poison was the cause, but did not give any special distinction. Leucocytoses were anæmic conditions, and resulted from a want of equilibrium between the production and the destruction of leucocytes. Obstructions of the spleen and liver by embolisms of the white corpuscles indicated the deposition of an excess of leucocytes in the organs rather than an increased formation of these elements in the points where they accumulated.

February 8. *Action of the Muscles in Dislocations.* M. Rigaud read a note on the function of the muscles in traumatic luxations. The conclusions were the following. The muscles never intervene directly to produce luxations. The consecutive displacements undergone by the luxated bones are produced by the action of the muscles. In the rational method of reduction by retrograde movement, they never do nor can oppose the replacement of the dislocated bones in their natural relations; on the contrary, they often aid it.

February 22. *Experiments on Animal Poisons.*—M. Chauveau forwarded a letter in answer to M. Colin's criticism on his experiments on virulent liquids. M. Chauveau maintained that whether the poisons were gradually and progressively diluted in an inert liquid, or the soluble parts of the solid particles were isolated, the same result was always obtained; the virulence was independent of the dissolved substances, and was related to the presence of suspended particles. The diffusion of albuminous liquids was effected when no membrane separated them. M. Chauveau had always seen that a layer of water of from 4 to 5 millimètres, placed in contact with vaccine lymph, speedily became albuminous, so as to coagulate by heat or nitric acid. Vaccine matter behaved like spermatic fluid submitted to gradual dilutions; neither the virulent property in the one, nor the fecundating property in the other, was impaired nor attenuated by dissolution, but simply dispersed here and there in the liquid mass. The corpuscular elements of glanderous pus, abundantly and repeatedly washed during forty hours and thus freed from any serosity which might serve as a vehicle, were as virulent as the entire pus. In the corpuscular elements, therefore, lay the activity of the virus. The meaning attached by M. Chauveau to his experiments did not go beyond this; he did not pretend to affirm anything in the essential nature of the virus. In conclusion, he claimed the priority of the discovery of leucocytosis in glands for MM. Christot and Kiener.—M. Colin recalled to mind that glanderous leucocytosis was pointed out twenty years ago by Delafond. As to M. Chauveau's diffusion experiments, they proved nothing; for he operated in capillary tubes in which capillarity necessarily intervened, and not diffusion alone. M. Colin operated with large tubes, and had never under these conditions been able to ascertain the diffusion of albuminous liquids; he had employed, in his experiments, vaccine lymph collected in sufficient quantity from numerous inoculations performed on bulls. As to washing, if the virulence belonged to

the corpuscles, all the washing waters as far as the tenth and upwards ought, according to M. Colin, to be virulent; since, according to him, they brought away a notable quantity of corpuscles.

Use of the Ophthalmoscope in Injuries of the Brain
M. Panas read a memoir on the study of circulatory disturbances visible by the ophthalmoscope in injuries of the brain, of which the conclusions were as follows. The papillary stasis (*Stauungs-papilla*) often shows itself after various injuries of the brain, as concussion, contusion, wounds, fractures of the skull, etc. It is not always accompanied by troubles of vision; therefore the fundus oculi should be examined in all persons who have received injuries of the head, whether there is or is not a lessening of their visual acuity. According to the necropsies which he had made, this stasis seemed to him to depend on the infiltration of the blood or serosity in the sheath of the optic nerve, and not on the cerebral lesion itself. The papillary stasis was not the indication of any special variety of cerebral injury, nor yet of its gravity; it only indicated the presence of a fluid effused into the meninges.

ACADEMY OF SCIENCES IN PARIS.

January 3. *Electric Currents*.—M. Chauveau continued his paper on unipolar excitation. He examined the physiological conditions which influence the character of the unipolar excitation of the nerves, during and after the passage of the current. He said: 'I have compared in four special cases, on a frog caught in the summer, the closing and opening contractions produced by unipolar excitation mediately performed with impolarisable electrodes. In the first observation the nervous system was absolutely intact; in the second, the spinal cord was separated from the encephalon; in the third, the nerve was cut above the application-point of the electrode. My studies on the mammalia have been up to the present limited to the mediate excitation of the facial nerve in the case of absolute integrity of the nervous system. The conclusions of these new researches are as follows. 1. Four types of contractions may be manifested during the passage of the current; *a*. Initial type, in which the effect of the current is only marked by a more or less instantaneous contraction, coinciding with the very moment of the completion of the circuit; *b*. Instantaneous continued type, in which an initial contraction more or less resembling the first type, is followed sooner or later by a generally irregular and imperfect tetanisation; *c*. Continuous decreasing type, or tetanisation, obtained instantaneously, then decreasing, sometimes slowly, sometimes with a certain suddenness; *d*. Permanent continued type with decided tetanus prolonging itself during the whole duration of the passage. 2. When the nervous system has not undergone any mutilation and does not present any further trace of the fatigue due to stimulation, the positive contractions produced by the passage of the current take on the initial type, with weak excitations, and the more or less permanent continued type, with very powerful excitations. The medium currents provoke contractions which belong to the intermediate types. It is with these last currents that the negative pole appears to have the greatest tendency to provoke tetanisation. 3. In these same physiological conditions of types, the contraction of opening shows a marked tendency to appear tardily. 4. A very re-

markable characteristic distinguishes the tracings taken in these thoroughly physiological conditions during the interruption period of the current. These tracings show that muscle then has a tendency to retain a more or less notable amount of the contraction which the passage of the current has imparted to it. 5. When the spinal cord has been separated from the encephalon, the phenomena of unipolar excitation resemble those of the preceding observation, except in one point; the persistence of the muscular contraction disappears almost entirely during the interruption period of the current. In the tracings, the fall of the curve of the contraction after the opening is more rapid, sometimes altogether sudden. This fall brings back the curve nearly to the axis of the abscissa. 6. If the spinal cord have been cut for a certain time, and the nerve be already fatigued, the contraction of the closing takes a clearly initial character, more or less instantaneous, even with strong positive excitations. Outside of the commencement of the opening and closing, the curve of the contractions is then a right line, losing itself in the axis of the abscissa, a right line on which the contraction of the closing and that of the opening, if it exist, appear under the form of more or less accentuated projections. 7. This last character manifests itself almost at once when the spinal cord has just been destroyed, but, in certain subjects, the tetanisation produced with strong currents by the application of the positive pole may be seen in this observation at the commencement during a very brief period. At this moment, the increase of the amount and of the duration of the positive contractions is observed when the current increases, almost as clearly as in the normal condition. Later on, the increase of the current becomes incapable of sensibly modifying the contractions. Positive or negative, strong or weak, these present all the same characteristics of amount or duration; except all the first, in which the superiority of the negative excitation is clearly retained. 8. Simple section of the nerve exercises a not less marked disturbing action of the same character as that of the crushing of the spinal cord, but the two actions differ in that the former, if the section of the nerves have been made before any preliminary application of currents, first temporarily gives rise to a remarkable inversion in the activity of the poles; it is with negative excitation alone that the contraction of opening is obtained, and this phenomenon coincides with the permanent preservation of the superiority of this negative excitation at the moment of closing. 9. In mammalia tetanisation is much more easily and promptly provoked than in the frog. It is, indeed, extremely well obtained by negative excitation by means of weak currents even with two small couples of Daniell's battery only, if electrodes of small resistance be employed. Rather stronger currents produce this tetanisation nearly equally in the case of negative or positive excitation. Finally, a sufficient increase of the current, by making tetanisation almost entirely disappear with the negative current, gives to that engendered by positive excitation a very remarkable character of permanent solidity. The tendency to the persistence of muscular contraction after the passage of the current, also exists among the mammalia, but in a much less marked degree than in the frog.'

January 10. *The Formation of Saccharine Matter in Animals*.—M. Claude Bernard communicated a paper on the formation of saccharine matter in ani-

mals. The author had long since demonstrated the presence of sugar in the normal condition in the blood; the glycogenic function of the liver under the control of the nervous system; finally, the almost diabetic condition of the fœtus. He had subsequently shown that the hepatic substance produced sugar not only by its action during life, but by chemical processes persisting after death.

January 17. *Formation of Sugar.*—M. Claude Bernard, in continuation of the subject, recalled to the mind of his hearers the experiment of the washed liver, which proved that sugar was formed in the liver, as in vegetation, at the expense of amylaceous matter. This experiment had induced Dr. Pavy to say that the presence of sugar in the liver is only a *post mortem* result. The presence of sugar in a great number of organs in the fœtus showed that the localisation of the glycogenic function only takes place after the complete development of the animal; but it could not thence be concluded that this function was general, since the glycogen was seen to accumulate in the liver of the fœtus in the same proportion as the sugar disappeared from the other organs.

The Cerebro-Spinal Nerve-Fibres.—A note by M. C. Sappey and M. Duval treated of the course of the nerve-cords which connect the brain with the spinal cord. Of the three columns which form the substance of the spinal cord, one is antero-internal, and separates the anterior median furrow from the anterior cornu. The antero-lateral column separates the anterior cornu from the posterior cornu. The posterior column goes from the posterior cornu to the posterior median sulcus. The antero-internal columns of the two sides interlace the whole length of the spinal cord, as far as the level of the medulla oblongata, which they pass through to become postero-posterior; they likewise pass through the cerebral peduncles and enter the optic thalamus. The antero-lateral columns only interlace after the antero-lateral columns; they go to form the deep layer or sensory portion of the pyramids; this sensory portion may be followed into the optic thalamus, where it accompanies the antero-internal fibres.

January 24. *A Case of Aphasia.*—M. Bouillaud communicated a case of aphasia arising from the loss of the co-ordinate movements necessary to the act of the pronunciation of words, without any lesion of the intellectual faculties. The patient had been suddenly attacked by paralysis of the right side and aphasia, and had retained his intelligence so that he comprehended all that was said before him, and all he read. He was able, after some days, to pronounce and write a few words.

REVIEWS.

The Anatomy of the Lymphatic System. Part II. The Lung. By E. Klein, M.D., Assistant-Professor at the Laboratory of the Brown Institution, London. Illustrated by 6 double plates of 27 Figures. 8vo. pp. 80. London: Smith, Elder & Co. 1875.

(Second and concluding notice.)

The second section of Dr. Klein's monograph is devoted to the pathological conditions of the pulmonary lymphatic system, which are dealt with under the three following subdivisions: 1. The changes in the pulmonary pleura in chronic diseases of the lung;

2. The relation of the lymphatics of the lung to the process of artificial tuberculosis in guinea-pigs; 3. The relation of this latter disease to acute miliary tuberculosis in man.

First, as regard the pleura pulmonum in inflammation: Just as in serous membranes—as has been stated by Dr. Klein in the first part of his monograph—the endothelium* here and there germinates, this action being much increased in inflammation, whether acute or chronic, so may similar sequelæ of inflammation be witnessed in the endothelium clothing the pulmonary pleura. The morbid action was set up by the injection of septic pus, or some similar morbid matter, by means of a Pravaz's syringe, or a capillary glass tube drawn out into a thin cannula, into the pleural cavity of the subject, be it rat, rabbit, or guinea-pig. In acute pleuritis of but short duration—24 to 72 hours—there is relatively little change in the endothelium of the pulmonary pleura. If, however, the animal be allowed to live beyond three days, groups of endothelial cells in the germinative condition, will be found arranged round a common centre in the shape of a hole, either empty or stopped by a plug. This centre is of the highest diagnostic importance, representing as it does a *stoma* through which absorption is going on; the fibrin of the pleuritic exudation being pumped into the stoma. Such change is of greater intensity if the pleuritis have become chronic, the germination of the endothelium round stomata being more distinct than in the acute condition of the disorder. The most typical specimens representing this change were obtained from the lungs of a guinea-pig, in which the injection into the pleural cavity of a minute quantity of septic matter from a tuberculous gland had produced artificial tuberculosis. Under such conditions, the costal and mediastinal pleura becomes in many cases, studded with numerous villous processes, covered by germinating endothelium, resembling similar papillæ found on the omentum and mesentery, as described in Part I. The pulmonary pleura, however, differs somewhat from the above, for, in artificial tuberculosis of long standing, the germination of the endothelial cells is spread over extensive areas, each cell being larger and more columnar, and its nucleus having undergone a double or treble subdivision. Nodular growths, too, standing in an intimate relation to the lymphatics, are frequently seen in the pulmonary pleura of the guinea-pig.

In the course of chronic pyæmia caused by the injection of septic matter into the pleural cavity, the pulmonary pleura of the guinea-pig in particular is seen to undergo three important inflammatory changes—*a.* a thickening of its matrix; *b.* hypertrophy of its muscular tissue; and *c.* certain changes in its lymphatics. These changes take place over areas corresponding to the nodular growths of the superficial parts of the lungs. The first named of these changes consists primarily of an infiltration with lymphoid cells, but later the matrix contains masses of bundles of fibrillar connective tissue, between which the lymph-canal system is well seen. The connective-tissue matrix of the pulmonary pleura has, in fact, simply become thickened, its structure having otherwise not undergone any marked change. We may, therefore, conclude that the increase of fibrillar connective tissue in the matrix stands in a genetic relation to the lymphoid bodies which, in the earlier

* In the former part of the review the word epithelium was used instead of endothelium, employed by the author.

stages infiltrate the pleura. The second change is perhaps, the most characteristic feature in the inflammatory process. The hypertrophy of the muscular coat of the pulmonary pleura consists in the approximation, by their thickening, of the bundles of unstriped muscles; and, as the morbid process advances, the muscular mesh-work already described (LONDON MEDICAL RECORD, vol. iv. p. 39, 1st column) may, by the abolition of the meshes over a large area, become transformed into an almost continuous membrane. The *rationale* of this hypertrophy is sufficiently obvious, for, as in other organs, so in the lung, obstacles to the carrying out of their normal functions, on assuming a chronic character, bring about a hypertrophy of the muscular tissue of the organ, if such tissue be essential to proper working. Since then the nodular growths just mentioned are great obstacles to the act of respiration, a compensatory hypertrophy of the pleural muscular coat is a sequel which we should naturally expect. There is, moreover, another reason for this process. In chronic pleuritis, artificially induced, the lymphatics of the pulmonary pleura, being charged with the products of inflammation, become less permeable, and the pleural muscular coat, materially adjunct to the free discharge of the lymphatics, undergoes, in compensation, hypertrophy. With regard to the third change brought about by the inflammatory process, whence originate the 'lymphoid cells' which frequently, in chronic pleuritis, completely plug up the subpleural lymphatic vessels of the lung in the guinea-pig? Some are doubtless due to the germination of the endothelium surrounding the stomata already described, while many are probably connected with the migration, the result of inflammation, of the blood-corpuscles, seeing that they are either pumped in from the exudation of the pleural cavity, or are absorbed from the very tissue of the pleura. If one of the nodular growths already mentioned be examined in a lung giving indications of advanced morbid changes, it will be seen to be made up of trabeculae and corresponding spaces. The trabeculae are probably the interalveolar rootlets of the subpleural lymphatics partly filled with lymphoid cells, and partly already in process of conversion into cords of adenoid tissue. Such adenoid cords formed within lymphatic vessels of the serous membranes have been described in the first part of Dr. Klein's monograph as 'endolymphangeal' follicular structures. The meshes between the trabecular plexus, which at a later stage are filled with bodies like lymphoid cells, are evidently the alveolar cavities. Similar nodular growths, which ultimately undergo caseation, are found abundantly on the superficial parts of the lung of guinea-pigs afflicted with artificial tuberculosis. Charcot and Debove have found that, subsequent to carcinoma of the breast, the lymphatics of the pulmonary pleura contained carcinomatous masses, which increase at the expense of the endothelium; and, according to Hillairet and Raynaud, there is to be found in connection with carcinoma ventriculi a general lymphangitis of the lungs and pleura.

The changes in the lung proper in artificial tuberculosis of guinea-pigs are next discussed. The researches of Dr. Burdon Sanderson and Dr. Wilson Fox have established the fact that the lung of guinea-pigs artificially inoculated with tubercle usually contains a new growth which is regarded as similar to miliary tubercle in man. After quoting

from the writings of these two observers, Dr. Klein passes on to his own investigations. Three kinds of granulation are found in the lung of a guinea-pig advanced in artificial tuberculosis; the one kind consisting of nodules more or less well defined in outline, being oval or spherical, which are also in connection with the wall of a bronchiole; the second comprising cord-like structures; while the third includes nodular structures of a conical or irregular shape. All these three kinds are of a peculiar semi-transparent appearance, the third kind only undergoing a cheesy transformation, indicated by an opacity in the centre. Two questions remain to be solved; viz., what is the structure and development of these bodies? and what is their relation to one another as regards the different stages of the morbid process?

1. The nodules found in connection with the bronchioles are analogous to the lymphatic follicles normally found in connection with the adventitia, which follicles are held by Dr. Klein, in accordance with the views of Dr. Wilson Fox and Dr. Burdon Sanderson, to become hyperplastic in artificial tuberculosis. Dr. Klein is not inclined to believe that these peribronchial follicles eventually undergo caseous degeneration.

2. The so-called 'cord-like' bodies, though easily confounded, on superficial inspection, with the nodular structures, are seen, on microscopical examination, always to bear a definite relation to a blood-vessel, surrounding it like a sheath; so that, when one of these is cut transversely, the blood-vessel in relation with it will also be seen in transverse section. The vessels with which these bodies are in such intimate relation are the minor branches of the pulmonary artery or vein, in the adventitia of which the new growth is situated, sometimes completely ensheathing the vessel, sometimes extending chiefly along one side of it. In advanced cases the perivascular cords extend as far as the point of junction of the pulmonary vessels with the bronchi, coming here into contact with the peribronchial granulations, with which they blend to some extent. All the perivascular cords agree in being composed of adenoid tissue, or one closely resembling this; but it is doubtful whether they, like the peribronchial lymph-follicles, possess a distinct system of blood-vessels. Next, as regards the development of the perivascular cords; the first step appears to be a distension of the perivascular lymphatics with plasma and lymph-corpuscles; then a reticulum of fibres makes its appearance, penetrating into the lumen of the lymphatic, and extending into the interalveolar tissue, thus converting the lymphatics into cords of adenoid tissue. Thus a structure is formed which was termed in the first part of this work 'endolymphangeal cord.' It is, moreover, probable that, as in the artificial tuberculosis of guinea-pigs, the lymphoid cells entangled in the fibrous meshes of the lymphatic cords are none other than migratory colourless blood-corpuscles, there being no evidence of their origin from the endothelial lining of the lymphatics. There may, however, be another method of origin of the perivascular lymphatic tissue, viz. by the formation of a 'perilymphangeal tissue,' by the extension into a collection of lymph-corpuscles, lying outside of a perivascular lymphatic vessel, of the fibres which are in close relation with the endothelium of that lymphatic. The mode in which a perivascular cord becomes developed, can, it will be readily seen, only be determined in the earlier stages of an artificial

tuberculosis. Concurrently with the changes to which the development of perivascular adenoid tissue is due, there takes place a germination of the endothelium of the ultimate branches of the pulmonary artery, which may go to such an extent that only a very narrow canal, just sufficient for the passage of a red blood-corpuscle, may remain of the lumen of the vessel, there being a considerable dilatation just above the point of stenosis. There is also very good reason to suppose that the coats of the pulmonary vessels are affected by the invasion of the perivascular cords in close contact with them; the capillaries even may not be exempt from change, being in some instances converted into solid nucleated threads.

3. The semi-transparent 'granulations,' of a more or less conical shape, and abundant in the superficial parts of the lung, are due, as Dr. Burdon Sanderson has described, to catarrhal pneumonia. In structure they are made up of trabeculae, representing the thickened alveolar septa, and in direct connection with the perivascular cords; and spaces filled with products of the alveolar epithelium. The epithelial lining of the alveolar cavities is of three kinds; *a.* granular and somewhat enlarged epithelial cells, including at most two nuclei; *b.* epithelial cells considerably enlarged, and containing several nuclei; and *c.* large masses of granular protoplasm, containing numerous nuclei, or, in other words, giant-cells, each of which is probably made up by the fusion of several epithelial cells. As might be expected from the compression and degeneration of the blood-vessels, the products of the catarrhal process finally undergo necrosis, *e.g.* caseation.

The last chapter of Dr. Klein's monograph is devoted to acute miliary tuberculosis in man. The author dissents from the assertion of Buhl (*Lungen-entzündung, Tuberculose, und Schwindsucht*, München, 1872) that, in all cases of acute miliary tuberculosis, the miliary tubercles are due to desquamative (*i.e.* lobular catarrhal) pneumonia. In the lungs of five true cases of acute miliary tuberculosis in children, Dr. Klein found the tubercular nodules to represent a number of alveoli distended by fibrinous material, including granules and small cellular elements; also that the trabeculae, *i.e.* the inter-alveolar tissue of the peripheral part of the tubercle, were slightly thickened, and contained lymphoid cells. The retiform tissue, in which a giant-cell may be imbedded, is not, according to Dr. Klein, as asserted by Buhl and Wagner, true adenoid tissue, but is either a network of elongated 'clumsy-looking' cells, or a network of fibrillar substance. With regard to the giant-cells themselves, Dr. Klein holds that not only such bodies in general, but those of tubercles in particular, have different modes of origin in different organs; and that, with regard to those under the latter category, there are only two alternatives of possible origin—from lymphoid corpuscles, *i.e.* colourless blood-corpuscles, supported by the observations of Ziegler, or from epithelial cells lining the alveolar cavities. The second is most commendable to Dr. Klein, since, among other cogent reasons, all intermediate forms may be found between well-developed giant-cells and nucleated cells of an undoubted epithelial character. That the giant-cells of tubercle of the lung are true cells, and that they may be isolated by teasing, Dr. Klein has repeatedly satisfied himself, being thus at one with Friedländer; and consequently he cannot accept Hering's view, that such bodies correspond merely to

a granular substance filling up the lumen of a lymphatic vessel, and that their nuclei are identical with the endothelial cells of that vessel.

As it would be presumptuous in any but a skilled worker with the microscope to criticise the correctness of Dr. Klein's observations, scarce anything remains to the reviewer save the literary style of the work. Now, since there is no room for elegance of diction in a bare description of microscopic minutiae, unrelieved by polemics flavoured with strong scientific odium or by theoretic flights of fancy, it is not unreasonable to expect, as a slighter substitute, some attempt at clearness and accuracy of description. But though, unfortunately, in Dr. Klein's monograph there are here and there passages which sorely try the patience of a reader who is doing his best to get at their meaning, great allowance ought to be made for the fact that the author has clothed his thoughts and observations in a tongue other than his own, and one which, only too frequently, is not without its difficulties even to a native. Having given utterance to this seemingly ungrateful and ungracious remark, it is a real pleasure to be able to praise without reserve the excellent and copious illustrations of the monograph, due, not only to the dexterous scalpel, but also the facile pencil of its author. To those who, with the reviewer, have almost despaired of seeing such work executed in this country, there will appear a faint gleam of hope, after seeing the plates, but little inferior to those just mentioned, which illustrate the same author's paper in the current number of the *Philosophical Transactions* of the Royal Society.

J. C. GALTON.

The Successful Treatment of Internal Aneurism, by Consolidation of the Contents of the Sac, Illustrated by Cases in Hospital and Private Practice. By JOLIFFE TUFNELL, President of the Royal College of Surgeons in Ireland, etc. Second Edition, pp. 71. Dublin: Fannin & Co. 1875.

The profession will welcome the reappearance of Mr. Tufnell's valuable and important treatise, comprising the contents of the first edition (of 1864), with additional confirmatory cases which were published in a paper on the subject in the fifty-seventh volume of the *Medico-Chirurgical Transactions*. A diligent comparison of the two editions would also discover a few additional observations on the details of diagnosis and treatment, but they are so few, and comparatively so unimportant, that the present edition may be regarded practically as a re-issue of the former, with five additional cases to prove the possibility of curing aneurism of the large arteries in the chest and abdomen in this manner. The subject is so very important, and the objects and method of Mr. Tufnell's treatment are still, after all that has been said about them, so imperfectly understood, that we shall make no apology for bestowing a longer notice on this little work than its mere size would at first sight seem to require. Mr. Tufnell justly says that his matter might easily have been expanded into a large volume. Busy practitioners will certainly not complain of a brevity which, while it saves their time, leaves nothing unsaid which the topic requires.

We will treat the subjects of Mr. Tufnell's treatise in the order we have indicated. First, what evidence does Mr. Tufnell produce that it is possible to cure aneurism of the aorta and its large branches in the

chest and abdomen by position and restricted diet? Second, what are the objects of his method? And, lastly, in what manner does he propose to secure them?

The number of cases which Mr. Tufnell brings forward to prove the possibility of cure by his method are eleven. They are as follows. 1. A case of aneurism of the abdominal aorta, as large as an orange, was cured in three months by rest and restricted diet; the patient, a carman, aged thirty-five, living and plying his trade for over four and a half years, when he was killed accidentally. As we wish to look at Mr. Tufnell's cases as critically as possible, we will add that, though it is evident that the symptoms in this case were so far mastered as to enable the patient 'to do all his work, with the exception of lifting a bucket full of water, which he found great difficulty in effecting, from inability to straighten his back,' there is no evidence that the aneurism was entirely consolidated. Mr. Tufnell says that at an early period of the treatment 'the tumour became partially solid, so that when grasped it imparted to the hand the idea of considerable density'; but he strangely omits all description of the final condition of the tumour. 2. The second case, (p. 11), is one which is less convincing, since neither are the grounds of diagnosis very fully stated, nor is there any absolute evidence of consolidation. The disease was believed to have been aneurism of the thoracic aorta (descending if we rightly understand), and the patient lost all symptoms after ten weeks' treatment, and resumed the duties of an ordinary seaman, but nothing further is known of him. The third case, (p. 12) is one of far greater value and importance. Here there could be no question of the existence of a very large aneurism of the arch of the aorta which had eroded the sternum and ribs, in a man aged fifty-four. All the symptoms, including the pulsation, subsided, and the large mass remained consolidated and pulseless, while the cutaneous veins of the abdomen enlarged and communicated with those running to the superior cava, showing the interruption of the deep circulation in the thorax. This man was seen, and a portrait of him is given, three years after the consolidation of the tumour, in Mr. Tufnell's first edition. We learn from that edition that the treatment commenced in 1854, and from the author's silence on the subject we infer that the man is still alive, and, if so, is seventy-six years of age. The *post mortem* examination of this man's thorax is almost a matter of public interest, and it would be a most regrettable circumstance if he has died in the interval and the opportunity has been lost. The fourth case (p. 16) is a well marked case of aneurism of the abdominal aorta, in which great improvement in the symptoms and some amount of consolidation of the tumour no doubt ensued, but where there is no evidence of absolute cure. The fifth case (p. 19) is one of striking interest and importance. It was also a case of abdominal aneurism. As the patient ultimately died from rupture of the aneurism, it is quite clear that a cure was not obtained; yet if it be not a paradox to say so, the case is almost more favourable to the treatment than one of complete cure would have been. The patient, believing Mr. Tufnell's diagnosis, at first followed his treatment with the effect of losing his symptoms and obtaining a very great amount of coagulation in the tumour. Then, unluckily for himself, he took the advice of other surgeons, who told him that he had never had aneurism and might indulge in violent exercise, and the consequence of following

that advice was fatal. The sixth case (p. 23) is also that of an aneurism of the abdominal aorta or of the *coeliac* axis, in which the treatment produced great amelioration and possibly a 'practical' cure, though some pulsation and a faint bruit still remained. All these cases were related in Mr. Tufnell's edition of 1864. The seventh case (p. 26) was one in which the patient had aneurism of the right common and left internal iliac arteries. He was lying in bed dying of dropsy, and after death it was found that the aneurism of the internal iliac was absolutely cured and partially absorbed, while that of the common iliac was in process of consolidation. The specimen is figured, and was exhibited to the College of Surgeons by the present reviewer in illustration of a course of lectures on Aneurism; but as the aneurisms do not seem to have been diagnosed before death, and as the patient's dying condition precluded the possibility of any treatment, the case bears only indirectly on Mr. Tufnell's subject. The eighth case, however (p. 27), is one of the greatest possible importance. Here an abdominal aneurism was completely consolidated under Mr. Tufnell's care and by the methodical employment of his plan of treatment, and the death of the patient shortly afterwards, from disease of the kidneys, enables the author to present in the frontispiece a faithful representation of an aneurism of the abdominal aorta, springing from that artery just below the *coeliac* axis, completely consolidated and filled with laminated fibrin, and in its cured condition larger than the closed fist. It is interesting also to note that all the branches of the aorta remained pervious. If this case had stood alone, the efficacy of Mr. Tufnell's method in curing internal aneurism might be said to be satisfactorily established by it. The ninth case, however, on p. 34, is hardly less convincing. It is that of an aneurism of the abdominal aorta in a patient of Dr. Carte, aged seventy-nine years, where the symptoms were relieved and the aneurism cured by three weeks of treatment—the man dying of old age more than three years afterwards, when *post mortem* examination allowed Dr. Carte to obtain the specimen, showing the definite anatomical proof of complete cure, the sac being wholly obliterated by laminated fibrine. The interest of this case is increased, if that be possible, by contrast with another subsequently under Dr. Carte's care, in which the symptoms were very similar, and the result might have been the same, but the man had not the patience to submit to the confinement, persisted in walking about, and died from the rupture of the sac in two months. The tenth case (p. 36) is one of aneurism of the thoracic aorta, where much relief was obtained from the treatment, but the patient returned to severe labour, and the aneurism burst. The eleventh case (p. 38) is one of popliteal aneurism (under the care of Dr. Muschamp) which underwent a cure under the employment of rest and restricted diet; but here, as the leg was 'raised upon a pillow and slightly bent,' the case approaches rather to those of cure by voluntary flexion which the present writer has published, and to which he alluded in a lecture delivered (June 19, 1874) at the College of Surgeons, in which he endeavoured to show that the cure by flexion does not necessarily involve any irksome confinement, but that, in simple cases of popliteal aneurism, a cure can be obtained by the patient merely keeping the limb in the bent position to as great a degree as is comfortable to himself, and allowing himself a relaxation of the posture when he finds it necessary.

Such is Mr. Tufnell's evidence, and we think that the following would be a fair summary of it, looking at it from the most critical point of view possible. The third case shows the possibility of complete cure in thoracic aneurism, the pulsation being certainly obliterated, and the sac, we can hardly doubt, completely consolidated. At the same time, it would increase the importance and interest of the case if an anatomical examination could be procured. The tenth case is also a valuable instance of the great amelioration and possibly the practical cure which may be obtained in thoracic aneurism, meaning by a practical cure, a sufficient consolidation to allow of the circulation going on through the aneurism as through the original artery, without any tendency to further increase. The second case would point in the same direction if the diagnosis were established. These are all the cases of thoracic aneurism. Of the seven cases of abdominal aneurism, two (Nos. 8 and 9), were completely consolidated, and the preparations are still in existence to show the reality of the cure. In Nos. 1 and 6 a practical cure seems to have resulted. In No. 5 the disease was nearly cured, and with ordinary prudence it seems likely that the patient would have completely recovered; and in No. 4 the symptoms were certainly relieved. The remaining case, No. 7, is rather an illustration than a case absolutely in point. If this is a correct statement of the evidence, it certainly must be admitted to afford a proof of the possibility of absolute cure, and of the probability of practical cure, in all aneurisms, even those situated close to the heart. And we can assure our readers, from a considerable personal experience of the method, that they will hardly ever be disappointed in the expectation of relieving the distressing symptoms of thoracic aneurism in this way, and that the relief will be the more complete, the more accurately the patient can be persuaded to submit to the treatment in all its rigor. It hardly needs to be added that, if this is the case with aneurism springing from the immediate neighbourhood of the heart, the prospect both of cure and of relief is greater in those situated further down.

We now pass on to the next topic. What is the object of Mr. Tufnell's treatment? It is usually represented as being the *diminution* of the circulation; and so to a certain extent it is, but equally or even more important is the *equalisation* of the circulation, *i.e.*, to keep the pulse for many weeks or months at a perfectly equable rate and volume. It may be very fairly questioned whether it is desirable, nay rather whether it is not injurious, to diminish the patient's powers and weaken his circulation too much. It is a common and a very probable opinion that the deposition of fibrin in the sac goes on better when the patient's blood is moderately rich and his vessels moderately full. But this is under the supposition that the circulation is in both cases equable. No one can doubt that frequent changes from extreme feebleness to the irritable reaction which necessarily follows it must be injurious, looking only to its effects on the tension of the sac. Nor can it reasonably be doubted that impaired nutrition must be very deleterious to the tissues which form the sac.* In every point of view, in fact, the treatment

which goes by the name of Valsalva appears to be theoretically unadvisable, and it certainly is entirely different from that which Mr. Tufnell proposes. We would refer to page 61 of this treatise for a clear and perfectly convincing demonstration of the absolute incompatibility in principle between the two methods.

Mr. Tufnell, on the contrary, endeavours to reduce the circulation slightly below the normal standard of frequency by complete and protracted recumbency. In order to ensure that the patient does not move from the horizontal position, his bed should be made completely comfortable, by attention to many minute details which are here faithfully set out; and, in order to avoid any straining from constipation, or any disturbance from diarrhoea, the state of the bowels must be carefully regulated, so as to procure a soft easy motion about every other day. Wakefulness or irritability must be soothed at first with chloral or morphia, very carefully administered, and the diet is to be restricted to about ten ounces of nutritious solids and eight ounces of fluid in the twenty-four hours, the fluid comprising, if necessary, a little wine. The patient ought in every case to be prepared for a period of total rest of not less than three months. In some favourable cases a shorter time may suffice, but it is far more probable that the surgeon will have to make a call on his fortitude for a longer period of endurance, and it is useless to deny that the ordeal is a severe one at first, and especially to persons accustomed to an active life, and destitute of mental resources. The deprivation of food, and even more so that of drink, is at first severely felt, and the minimum must usually be reached gradually. But to most people the confinement is even more trying. Still the majority can be induced to give a fair trial to the method, and the present writer feels himself justified in asserting broadly that, with the exception of a few hopeless cases, where death was already imminent, and the patient sank rapidly, he never saw one in which the treatment was not followed by very great improvement; and two cases, at any rate, of aortic aneurism are now under his observation, in neither of which would the patient have been expected to live a month when first seen, and which are now alive and improving, in one two years, and in the other more than one year, after the commencement of treatment. In both these instances it is his conviction that life was preserved solely by the prolonged use of Mr. Tufnell's method. That a complete or anatomical cure of aneurism of the arch of the aorta should often occur seems very improbable, but it is his deliberate conviction that the sac might be comparatively often so far filled with fibrine as to produce what is called above a 'practical' cure, if the treatment by rest and restricted diet were used more methodically and with an intelligent perception of the necessity for attention to the numerous details which Mr. Tufnell here describes.

In conclusion we may say a word or two on the comparison between Mr. Tufnell's and other methods of treatment. While fully sensible of the advantages which in some cases follow the employment of galvano-puncture in aortic aneurism, personal experience,

* We hope we shall not be considered tedious if we again repeat what we have often said before, as to the very small part which the sac plays in the ordinary descriptions of aneurismal tumours. Most writers speak only of the behaviour of the contents of the sac—writing about aneurisms as if they were bladders of dead tissue filled with blood—which will

break if the pressure on them is too great, but which have no vital actions of their own. It is, on the contrary, our conviction that the rupture of an aneurism is more often the consequence of such vital action in the sac than of mere pressure. It is obvious, if this is so, that starvation by its injurious influence on the nutrition of the sac must much increase the risk of rupture.

as well as the study of the writings of Signor Ciniselli the great authority on this subject, has deeply impressed the writer with a conviction of its uncertainty and its danger. Much more may this be said of the introduction of foreign bodies into the sac. The method of Mr. Tufnell, on the other hand, is free from all danger of its own. The only risk connected with it is the risk that the disease may still make progress, and a week or two's observation will settle this point. It is only in those cases of thoracic aneurism in which the disease is advancing under Mr. Tufnell's treatment, or where that treatment has been fully tried and failed, that the propriety of more active interference should even be discussed. We are also disposed to say the same (though of course with much more hesitation) of those cases of abdominal aneurism in which compression of the aorta under anæsthesia is possible, and certainly when the disease extends high up. In spite of the splendid success obtained in Dr. Murray's and other cases, we now know that the proceeding involves very great immediate risk, partly from the protracted administration of the anæsthetic, partly from the risk of contusing the viscera or the aneurismal tumour, and may of course fail after all. Mr. Tufnell's method involves no such risk, hardly ever fails at any rate to diminish the volume of the aneurismal tumour, renders the patient no less able to support the compression afterwards, if it be found necessary, and will, we believe, often supersede the necessity for the employment of more dangerous measures. We congratulate Mr. Tufnell on the extended appreciation which his method has already secured, and we believe it would be a source of legitimate congratulation to the public if that appreciation should become so universal as to render it the rule of practice to adopt this method of treatment in all cases of aneurism in the chest and the great majority of those in the abdomen.

T. HOLMES.

On Stethometry. Being an Account of a New and more exact Method of Measuring and Examining the Chest, with some of its Results in Physiology and Practical Medicine. By ARTHUR RANSOME, M.D., M.A. (Cantab.). London: Macmillan and Co. 1876.

The author of this work has entered upon a field which in Britain is almost unoccupied, namely, the application to the study of diseases of the chest of the graphic method, and other instrumental means of exact measurement. There is one important respect in which the respiratory movements offer much greater facility for registration than those of the heart or pulse. For, owing to the comparative slowness and magnitude of the motions, and the greater force by which they are produced, it is needless to give to the recording instrument either the lightness and delicacy, or the amplifying power which is necessary in the sphygmograph or cardiograph. Thus there is no danger of any error being introduced in consequence of the acquired velocity of a lever, or the oscillations of a spring. On the other hand, the movement of the chest is not one of simple expansion, but is made up of components in three directions, the separate recording of which presents considerable mechanical difficulty. Thus other observers have contented themselves with representing some one element of the motion; Marey having chosen the variation of the circumference, Burdon

Sanderson that of a single diameter, and Riegel the forward movement of the front of the chest. Dr. Ransome has been the first to invent an instrument, the three-plane stethometer, by which the extent of the motions of any point in three directions, upward, forward, and outward is simultaneously registered. The patient sits upright in a chair, while the instrument is placed on a table before him, and the pad of its lever is so adjusted to a rib, or to any other part, that it readily follows its every movement.

The author has also devised another instrument, the stethograph, by which not merely is the extent of motion registered, but the actual path of each point is graphically described. For this purpose the outward motion, which is comparatively small and unimportant, is eliminated, and the curve described is that made up of the combined forward and upward movement in a single complete inspiration and expiration. Thus in both instruments the record applies to a single cycle only of respiratory action, and in the stethograph the motion is not magnified, but depicted in its actual extent. It is scarcely applicable therefore to the very slight motion which takes place in natural breathing, and all the examples in the work are taken from forced respiration. The three-plane stethometer may be converted into a stethograph by adapting the motions of its three dials to drums, by which the movement is conveyed to the levers of a revolving cylinder. Dr. Ransome gives four examples of tracings thus obtained, but all the rest of the material upon which his work is based was obtained by means of the simpler instruments. In its original form the three-plane stethometer is admirable in its simplicity and accuracy; but converted into a stethograph it would become somewhat complex and costly. Hence, for obtaining the curves of a series of respirations, natural or forced, the stethograph of Dr. Burdon Sanderson, or the still simpler instrument of Riegel, by which simultaneous tracings of two points on the chest may be taken, would seem to be more convenient. The only criticism which we have to offer on the results of Dr. Ransome's observations is, that he has limited them to forced respiration, and has not given the comparative effects of natural breathing, which might have been obtained by means of the three-plane stethograph.

The author has devoted considerable attention to the evidence to be derived from his instruments with regard to the physiology of respiration. He finds that the curves described are not to be accounted for by supposing that the ribs simply move upon their articulations. For, if the inclination of a rib and its chord-length be known, the relative amount of forward and upward movement produced by such an action can at once be calculated. Dr. Ransome determines the inclination of the rib by means of a special goniometer invented by himself, and finds that the amount of forward movement is far greater than can be thus explained. There must, therefore, be a diminution of the curvature of the ribs in inspiration, and consequent increase of their chord-length. This he considers to be chiefly due to the release of the elastic ribs from a strain placed upon them in expiration, but partly also to some effect of muscular action or tonicity during inspiration. It is the forward movement which is chiefly diminished when there is any disease of the lung beneath, especially when it is at all acute in character. Thus is shown an effort of nature to afford local rest by the suspension of muscular action, and an indication is

afforded for carrying out the same object by means of artificial supports.

Numerous examples are given of the practical use of the stethometer in disease. In emphysema and bronchitis the impairment of motion is very great, and its degree is here an exact measure of the extent of the disease. In the later stage of pleurisy, valuable information is obtained as to the extent of mischief done, and the progress towards recovery or otherwise. But it is in phthisis that the most valuable application of the stethometer is found. Not only does it afford a means of numerically recording the amount of disease present, and so registering its rate of progress; but in some instances it is found to show signs of commencing mischief when it cannot be detected in any other way. The author considers that it will also prove very valuable in prognosis; for he finds that the stage of disease being the same, there is much more impairment of motion in acute than in chronic cases. It will be seen that a wide field of research is thus indicated for other observers to assist in exploring.

NEW INVENTIONS.

MAGNESILYNE.

This new preparation, manufactured by Messrs. Benmond & Co., of Leamington, is intended to take the place of citrate of magnesia, a compound which recent investigations have tended to bring into disrepute, from the proved nature of its constituents, as commercially manufactured and sold. Messrs. Benmond guarantee their magnesilyne to contain 60 per cent. of ordinary crystallized citrate of magnesium, in combination with citric acid, bicarbonate of sodium and sugar. It is perfectly soluble and effervescent, and will be found an useful and agreeable form for administration in cases where a mild aperient saline is demanded.

THE UNIVERSAL DISINFECTING POWDER.

This new disinfecting powder meets a great public want. It is cheap, highly effective, and free from the danger of producing accidental poisoning to which other well-known disinfectants give rise with such lamentable frequency. It is perfectly soluble, colourless, and free from odour. These are qualities to make it valuable for daily and popular use. It is manufactured by Messrs. Ledger and Co., Lant Street, Southwark. It has been found very effective by many medical officers of health who have practically tested it, and has been favourably reported on by Mr. Wanklyn and Mr. Bartlett, two of our most eminent experts in the chemistry of disinfection, and will now no doubt find its way into popular use in towns and rural districts, and in ships, hospitals, slaughter-houses, stables, etc.

RECENT FRENCH BOOKS.

MISCELLANY.

THE SWISS LAKE-DWELLERS.—A Zürich paper reports a discovery which throws light on the hitherto obscure question as to how the lake-dwellers disposed of their dead. Between Auvernier and Colombier, in the vicinity of two lake-dwellings—one of stone, the other of the bronze age—house-building excavations have brought to light a chamber supported by upright stones, and containing ten or fifteen skeletons, the skulls collected in one corner, the other remains in the centre. Near them were found a bear's tooth, a wolf's tooth, half a boar's tooth, a small smooth bone-disc, two hatchets of serpentine stone, a bronze needle (all these bored through) a small copper ring, and four small bronze child's bracelets. It is supposed to be a family grave of a date transitional between the stone and the bronze ages.

AWARDS.—Professor Huxley was awarded the Woolaston Medal at the anniversary meeting of the Geological Society in recognition of his services to geological science. At the same time the Murchison Medal was awarded to Professor Selwyn, and the Sir Charles Lyell Medal to Professor Morris.

MEDICAL CERTIFICATES.—A criminal condemned to the guillotine had an attack of fever, and was in bed when the executioner made his appearance. The sick man exclaimed that he wished to see the doctor. 'The doctor! No, it is the chaplain you mean.' 'No, no; I mean the doctor. I want him to certify that my state of health will not allow me to undergo the operation.'

BLOOD-LETTING IN MEXICO.—According to Mr. H. H. Bancroft ('The Native Races of the Pacific States of North America') the doctors of a Mexican tribe perform venesection in a very original way. The patient stands upright and naked before the operator, who sticks him with arrows until the point of one of them has opened a vein.

DISEASES OF MODERN LIFE.—Dr. B. W. Richardson, in his recent courses of lectures on the diseases of civilisation, speaks of a new form of poisoning which has within the last two years manifested itself amongst the men employed in the refining of crude paraffine. It generally appeared, in its first stage, as an eruption of bright red pimples upon the exposed portions of the workmen's skin, and it was purely an affection of the hair-follicles, caused by the inflammatory properties of the crude paraffine oil when it penetrated the skin.

THE IDENTIFICATION OF BODIES.—An important and highly praiseworthy improvement is about to be introduced at the Morgue. In future the corpses taken thither are not to be exhibited in a state of nudity, but in their 'habit as they lived.' As people are not in the habit of seeing even their nearest relatives in a state of nature, friends will have less trouble than heretofore in recognising and identifying the bodies when they are clothed; and the new regulation will do away with the dealing in articles of apparel which has already brought several warders of the Morgue before the Police Correctionnelle.

THE TRANSFUSION OF BLOOD.—The following extract, bearing on this subject, will be found in 'Pepys' Diary' (Nov. 14, 1666), p. 339 of Warne's edition. 'Dr. Croone told me that at the meeting at Gresham College to-night (which, it seems, they have now every Wednesday again) there was a pretty experiment of the blood of one dog let out (till he died) into the body of another on one side, while all his own ran out on the other side. The first died upon the place, and the other very well and likely to do well. This did give occasion to many pretty wishes, as of the blood of a Quaker to be let into an Archbishop, and such like; but, as Dr. Croone says, may, if it takes, be of mighty use to man's health, for the amending of bad blood by borrowing from a better body.'

COST OF LUNATICS IN ASYLUMS.—The Commissioners in Lunacy have taken the average cost of maintaining the insane in county and lunatic asylums during the year 1874. These institutions are found in all parts of the kingdom: varieties of cost, due to the difference of local markets, are of course eliminated by the average. The articles consumed and the services required were supplied to more than 32,000 persons—the patients of fifty-four county and borough asylums. The average weekly cost in the county asylums, numbering in all forty-seven separate establishments, was 9s. 11½d. per patient; the average weekly cost in seven borough asylums was 11s. 8d., or rather more than 1s. 8d. per head in excess of the county charge. Taking the extremes in county asylums, it is found that at Dorset the cost is 8s. 2d., or 1s. 9½d. below the average; at Northumberland it is 12s. 1½d., or 2s. 1½d. above the average. In the boroughs the extremes are still wider; Birmingham expended at the rate of 8s. 6d. per patient, while the City of London paid 15s. 0½d.

A SHOWER OF WORMS.—The *Morgenblad* of Christiania states that after a recent violent storm a number of worms were found crawling on the snow, and it was impossible to find the places from which they had issued, everything being frozen in the vicinity. Similar circumstances were reported from several places in Norway.

RAREFACTION OF THE AIR.—M. Paul Bert has offered a prize for the best means of protecting the lives of aeronauts and mountain-climbers in circumstances where cold and rarefaction of the air become dangerous. The prize offered by M. Bert is a 20l. gold medal, and the competition is open up to December 31, 1876.

THE MEDICAL SOCIETY OF LONDON.—The 103rd anniversary meeting of this society was held on Wednesday last, when Mr. William Adams, F.R.C.S., of Henrietta street, Cavendish square, was chosen president for the ensuing year. The silver medal in the gift of the society for the best paper of the year was awarded to Dr. T. Lauder Brunton, F.R.S., of St. Bartholomew's Hospital.

ENGLISH MEMBERS OF THE INSTITUTE OF FRANCE.—According to the *Annuaire* for 1876, there appear to be five English Academicians and twenty-nine English correspondents of the Institute of France. As Academicians in Science are Professor Owen and Sir G. B. Airy; as correspondents in the Class of Science are Professors Sylvester and Adams (Cambridge), Sir T. Maclear, Rear-Admiral Richards, General Sabine, Dr. J. P. Joule (Manchester), Dr. E. Frankland, Professor A. W. Williamson, Professor W. H. Miller (Cambridge), Dr. Hooker (Kew), Dr. W. B. Carpenter, Dr. Huggins, and Mr. Lockyer.

PROFESSOR HUXLEY ON EVOLUTION.—In a lecture delivered in the City Hall, Glasgow, on the 17th ult., on the subject of 'Teleology and Morphology, as Illustrated by the Hand,' Professor Huxley described teleology as the argument from design, and morphology as the science which had to do with what was called the unity of the organisations of animals, as the result of their gradual modification. Illustrating his remarks by the human hand, he stated at length that in a certain sense, with certain limitations, the teleological argument was a valid one, though, as far as he was concerned, he did not ascribe to it the same vitality as some persons might do. As a matter of fact, he contended that the animal creation was evolved, not constructed in the way the teleological argument was stated by Paley; but, notwithstanding, he held that the two lines of argument were not inconsistent the one with the other, and that a man might be a teleologist, but at same time hold all the doctrines of morphology.

A NEW GAS BURNER FOR LABORATORIES.—The low pressure of gas which prevails during the day-time in many places causes not a little inconvenience in the use of Bunsen burners of the usual form, as these are liable, under such conditions, to retreat when moved slightly, or when exposed even to such moderate currents of air as are produced by the motion of a person walking past them. To obviate this inconvenience, which he had experienced in his own laboratory, President Morton, of Hoboken, has devised, says the *Journal of the Franklin Institute*, a burner which seems to meet the difficulty in a simple but scientific manner. Considering that the retreat of ordinary burners was occasioned by irregularities of the nature of eddies in the flow of the ascending explosive mixture, by which its rate of ascent was reduced locally below that at which such mixture would burn downwards, he draws in the upper end of the main tube so that the mixed gases escape through what may be regarded as an aperture in a thin plate. This presents, as is well known, the conditions requisite for a smooth vein in the case of liquids, and inferentially in that of gases. In fact the burners so made have proved very satisfactory in actual use. The large burners will work under very low pressures, and smaller ones may be burned down until actually extinguished, without any adjustment of air supply, and yet without possibility of retreating.

The London Medical Record.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

BURRESI ON A CASE OF WOUND OF THE SPINAL CORD.

The following case, published by Dr. Pietro Burresi, of Siena, in *Lo Sperimentale* for November 1875, is of interest in consequence of the careful observations made on the functions affected by the injury.

Didaro Tanzi, aged thirty-three, was admitted into the hospital in Siena on May 10, 1875. On the evening of February 9 he had received in a quarrel, while stooping to pick up his cloak from the ground, a wound with a knife between the first dorsal and last cervical vertebræ, a little to the right of the middle line. He said that the blade was a little larger than an ordinary penknife. Immediately on receiving the wound, he fell; but remained perfectly conscious. It seemed to him, he said, as if both lower limbs and the left upper limb, as well as the belly and the left side of the trunk, were enormously increased in size, and that the skin covering them was distended to the utmost. Tactile sensibility was unaffected; he distinctly felt the ground on which he lay, as well as his clothes, and the arms and hands of those who lifted him. The lower limbs and left upper limb were quite motionless; and the right arm, although its movements were free, was too weak to be used in the slightest degree for the purpose of defence.

He was carried to the hospital, and treated in the surgical department. The sensation of distension remained more than thirty days, during which time he could not move the lower limbs at all, and the right arm only slightly. After the healing of the wound, electricity was applied. He almost completely recovered the use of the right limbs; and the paralysis of the left leg was improved. On April 28, he left the hospital, walking on crutches, and dragging the left foot. On May 10, not satisfied with the progress he was making, he returned to the hospital, and was admitted into the medical clinic, where the following observations were made.

Inspection.—The whole of the muscles of the left side, both of the limbs and the trunk, were rather thinner than those on the right; and this difference was greater in the lower limbs. The costal excursion in breathing was small; it was rather greater on the right side, so that there was distinct obliquity of the respiratory movements. While he lay on his back, the left leg and foot were slightly turned outwards, the right remained in the normal condition. If the patient were desired to bend the left knee, it was seen that he was able to bring the left foot into the normal position. When desired to raise his legs from the bed and place them at a right angle with the body, he raised the right limb with great power and readiness, kept it raised for some time, and then replaced it with ease on the bed. The left leg

was raised very slowly, and was with difficulty, or rather not at all, brought to a right angle with the body; it was kept up for a shorter time than the right, and oscillated and was turned inwards; he could perform abduction, adduction, flexion, etc., while the limb was raised, but could not replace it on the bed so steadily as he had done with the right.

When he stood erect, the left leg would not support the weight of the body without crutches. In walking, this leg was raised from the ground more than was necessary; the heel was not pressed thoroughly on the ground, even when it was the turn of the left foot to bear the weight of the body. The point of the left foot was, in walking, always turned downwards and a little inwards.

When blindfolded, he could not move a step; he had no further knowledge of the direction which he should take; the left foot was raised several centimètres, and the patient did not attempt to place it on the ground, but rested entirely on his crutches and would have fallen if not supported. His eyes being still bandaged, a sheet was spread on the floor, and the patient was led barefooted on to it; with the right foot he perceived that a body was interposed between the sole of the foot and the ground, both when he was walking on the bare floor and on the sheet; the sole of the left foot only felt a strong sensation of cold, both on the floor and on the sheet. When the bandage was removed from his eyes, he was astonished to find that he had been walking alternately on a sheet and on the bare floor. On his return to bed, it was noticed that the left lower limb, especially the leg and foot, was intensely red, and the whole left side felt distinctly colder than the right. The patient said that these phenomena always occurred when he walked; and that œdema of the left lower limb was readily produced.

The voluntary movements of the upper limbs were performed with ease, and were almost equal on both sides.

The cicatrix of the wound, about one-third of an inch in length, was about four-fifths of an inch to the right of the middle line. There was another scar at the external margin of the scapula in the posterior axillary line.

Palpation of the first-named cicatrix produced a little pain; it was not adherent to the subjacent tissues, nor could any signs of inflammatory exudation be detected near it. Palpation and percussion of the vertebral column did not produce any symptoms worthy of remark; nor did the application of sponges dipped in hot water along the spine. The whole of the muscles of the left side of the trunk and left limbs felt more flaccid than those of the right side; the difference being much marked in the left lower limb. The measurements of the lower limbs were as follows: immediately beneath the great trochanter, right, 49·5 centimètres; left, 47; above the patella, right, 34; left, 32; at the centre of the calf of the leg, right, 33·5; left, 30. Of the arms, the measurements were over the centre of the biceps, right, 25·5 centimètres; left, 24; above the elbow, right, 25·3; left, 24.

The grasp of the right hand was powerful; that of the left considerable, though much less.

Sensibility of contact.—The sensibility of contact of the surface of the body was tested by touching the skin lightly with a small piece of paper; it was found slightly diminished on the right side from the anterior inferior spine of the ilium to the foot: over the

remainder of this side it was normal. On the left side the contact sensibility was a little exaggerated, especially in the whole of the lower limb. There was perverted and exaggerated sensibility in the left little finger; when the outer border of this finger was touched with a piece of paper, the patient imagined that he had been touched with a pointed steel instrument, and forcibly withdrew the limb; the uncomfortable sensation continued for some seconds. The patient said that he felt formication, itching, etc., in the same finger and in the adjoining one.

Sensibility to pain was tested by slightly pricking the patient with a pin. On the right side, from the second intercostal space to the dorsum of the foot, the patient said that he felt that he was being touched, but could not distinguish when he was pricked with the pin; he did not feel pain, but simple contact, even when blood was caused to flow. Above the second intercostal space, in the right subclavian region, in the right side of the neck and face, and in the whole of the upper limb, he not only felt the punctures perfectly, but could distinguish the instrument with which they were made. In the whole of the left lower limb, in the left half of the trunk and in the left upper limb, pricking, although slight, produced intense pain and excited violent and continued reflex movements; this exaggeration of sensibility was greatest in the ring and little fingers. The hyperæsthesia was limited by the second intercostal space; above this, sensibility was normal. Posteriorly, there was the same analgesia of the trunk and limbs on the right side, limited above by a transverse line drawn across the fifth dorsal vertebra; and the hyperæsthesia of the left side extended to the same height. The hyperæsthesia and analgesia of the trunk were distinctly separated by the median line, and it was curious to observe how abrupt was the transition from analgesia to hyperæsthesia or *vice versa*, when the puncture scarcely passed beyond the median line on one side or the other, both in front and behind.

Thermic sensibility.—This presented modifications corresponding in extent with those of sensibility to pain. On the right side, the patient could not distinguish cold from heat at any part below the second intercostal space in front, and the level of the fifth dorsal vertebra behind; above, the thermic sensibility was normal. On the left side, the patient could not only distinguish heat from cold, but moderate temperatures were perceived in an exaggerated manner, warm substances appearing to be boiling, and cold ones freezing; this sensation was much more intense in the left arm, and especially in the left little finger. Above the limits already indicated, the thermic sensibility was normal, as on the right side.

Sensibility to tickling was retained; but on the left lower limb the reflex movements which it produced were exaggerated.

Electric sensibility and contractility.—To test these, a Gaiffe's electro-magnetic apparatus was used, the positive pole being applied to the spine a little above the cicatrix between the last cervical and first dorsal vertebrae, and the other pole alternately to the right and left sides of the body. The muscular contractions were very powerful on the right side, and were attended with slight pain; on the left side the contractions were also very intense, and great pain was produced at all the points to which the pole was applied.

Local sensibility.—When Weber's æsthesiometer was applied to the dorsum of the right foot, the right leg and thigh, and the right half of the trunk, the patient could not distinguish the two points when two centimètres apart. Above the second intercostal space, the patient felt the two points at a distance of one centimètre ($\frac{1}{39}$ inch); and in the whole of the right upper limb he recognised two punctures made simultaneously at a distance of two centimètres ($\frac{1}{8}$ inch). In the whole of the left lower limb, when the points of the instrument were less than two centimètres apart, the patient perceived sometimes one, sometimes two points at the same time; he also often had an indistinct feeling of formication, which was readily confounded with the painful sensation produced by the needles of the æsthesiometer. When the points of the instrument were two centimètres apart, he distinctly felt both at the same time, and an exaggerated sensation of pain, and reflex movements were produced. He also felt the two points when two centimètres apart in the whole left side of the trunk and left arm, especially at the outer margin of the little finger; and the sensation here was so exaggerated as to induce strong reflex movements of the finger and of the whole arm, and to leave a feeling of numbness for several minutes.

Muscular sensibility was tested by Jaccoud's method. With the right lower limb the patient perceived a difference in weight amounting to five grammes (77 grains); with the left, a difference of three grammes (46 grains). Muscular sensibility was very torpid on the right side, for, when weights of from two to ten grammes were added on that side, while no addition was made on the left, the patient always thought that he was sustaining a greater weight with his left foot than with his right. He had the same idea even when a kilogramme was placed in the bag attached to the right foot, and half that weight in the bag attached to the left; and, when 200 grammes more were added on the right side, he still thought that he was supporting a greater weight with the left foot.

During all the above-mentioned experiments, the patient was blindfolded.

[The result of the examination of the thoracic and abdominal organs is here given. It presents nothing special. The patient's general health was good.]

On May 16 treatment was commenced. The cold douche was applied along the spine once daily, and the electric current, by means of Gaiffe's apparatus, for ten minutes every morning and evening. On the left side, the negative pole was applied along the spine, and the positive to various parts of the lower limb; on the right side, the poles were applied in the reverse way. Pills containing 30 centigrammes (4.6 grains) and 2 centigrammes (0.3 grain) of alcoholic extract of *nux vomica* were given twice daily; and abundant nutritious food with wine was ordered.

On June 4, the patient was able to support himself well on his feet, making but little use of crutches. On June 7, the electricity was suspended for a time, in consequence of pain in the right loin and leg. On the morning of June 9, another examination of the patient was made, with the following result.

Inspection.—The patient easily raised both legs from the bed, but the left could not be brought to a right angle with the body. The patient could, however, lower both legs to the bed slowly and steadily. The greatest circumference of the right thigh was 49 centimètres; of the left, 47: of the right leg, 33 centimètres, of the left, 30.5. The greatest diameters

of the right arm and forearm were a centimètre more than on the left side.

Contact sensibility was very acute on the left side; on the right, it was absent from the foot to the knee, doubtful from the knee to the groin, and very weak from the groin to the second intercostal space.

Sensibility to tickling was very low on the right side; tickling of the sole of the right foot produced scarcely any reflex movement. On the left side, strong and extensive reflex movements were produced by tickling.

Sensibility to pressure was weaker over the whole of the right side than on the left.

Sensibility to pain was almost absent on the right side from the foot to the knee; from this point up to the second intercostal space it was much diminished; on the left side it was exaggerated. The upper limits of the hyperæsthesia and analgesia were the same as on the previous occasion; and the separation at the middle line was well marked.

Local sensibility.—In the left lower limb, the patient distinguished the two points of the æsthesiometer at a distance of two centimètres; on the right, he did not.

Thermic sensibility.—On the right side, a piece of ice felt moderately warm; but a temperature above freezing-point was recognised a little better. On the left side, thermic sensibility was very acute.

Muscular sensibility.—With the right lower limb, the patient distinctly perceived a difference of weight amounting to two grammes; he also perceived the same difference with the left limb, though perhaps less decidedly.

The patient generally walked with crutches; but he could walk with one crutch and a stick. He could stand on his feet, even with his knees bent.

On June 14, the patient could walk without crutches or stick, supporting himself merely by another person's hand. He got into bed by himself with ease. On June 22, he abandoned his crutches altogether, and walked with a stick only. On June 25, he was again examined, and the following observations were made.

Inspection.—The left lower limb was still less nourished than the right. He could easily raise both legs from the bed to a right angle with the body, and with equal ease and steadiness replace them on the bed.

Palpation.—The muscles of the left thigh and leg were a little more flaccid than those of the right limb. The circumference of the thighs at the thickest part were, right, 49 centimètres; left, 47: of the legs at the calves, right, 33 centimètres, left, 30.5. The right arm at the thickest part of the biceps measured 25.5 centimètres; the left scarcely 25. The right forearm had a circumference of 24.5 centimètres; the left, 23.5.

Tactile sensibility was very acute on the left side; on the right, it was greatly increased, and almost normal.

Sensibility to pain was greatly increased on the whole right half of the body, but was still a little less than on the left side. On the left side, the hyperæsthesia had almost entirely ceased, and the reflex movements, though greater than on the right, were less intense than before. The limits of the hyperæsthesia and analgesia above and on the middle line still existed.

Thermic sensibility was still imperfect on the right side. A piece of ice passed over the limbs and trunk and over the scrotum on that side gave a

doubtful sensation of warmth; while in the corresponding parts on the left side the same application produced a very acute sensation of cold.

Sensibility to pressure was normal on both sides.

Sensibility to tickling was very slightly obtuse on the right side; on the left it was very acute, but it did not produce the violent reflex movements noticed at the previous examination.

Local sensibility.—On the left side, the patient perceived two points two centimètres apart, and punctures at a less distance. On the right side, the points of the æsthesiometer were perceived only occasionally, on a limited part of the dorsum of the foot, at the distance of two centimètres.

Muscular sensibility.—With the right foot, he perceived distinctly a difference of two grammes in weight. With the left foot, he could not perceive it accurately, on account of soon becoming wearied.

He was able to walk with a stick, sometimes, but rarely, dragging his left foot on the ground.

On June 26, he returned to his home, where he continued the medicine, and used the electricity once daily.

On September 11, when the paper was written by Dr. Burresi, the following was his condition.

The left lower limb was still thinner and more flaccid than the right. Both legs were easily raised from and replaced on the bed; but the left limb trembled slightly when elevated. The left leg was slightly colder than the right. The measurements of the limbs in centimètres, taken as before, were: right thigh, 49; left, 47: right leg, 35; left, 32: right and left arms, each 24: right forearm, 26; left, 25.

Tactile sensibility was very acute over the whole of the left side. From the front of the right foot to about half way up the leg it was slightly imperfect, since occasionally the patient did not distinctly perceive the body with which he was touched; over the rest of that side it was normal.

Sensibility to pain was normal in the right lower limb; in the left it was a little higher. The previous local limits between lowered and excessive sensibility still existed, but now only denoted the passage from normal to a very slight degree of exaggerated sensibility. Pricking the soles of the feet produced reflex movements of moderate intensity, very little greater on the left side than on the right.

Thermic sensibility was normal on the left side, but on the right he could not distinguish cold from heat, and very often confounded one with the other.

Sensibility to pressure was normal everywhere.

Sensibility to tickling was normal on both sides. When the soles of the feet were tickled, reflex movements of normal intensity were produced.

Local sensibility.—In the right lower limb, the patient almost always perceived two distinct impressions at the distance of a centimètre; always, and very distinctly, at the distance of a centimètre and a-half. On the right side, the two impressions were perceived distinctly at a distance of a centimètre and a-half, and occasionally—less frequently than on the left—at the distance of a centimètre.

Muscular sensibility.—Two empty bags being placed one on each foot, the patient said that the left was the heavier. When a weight of ten grammes was added on the right side, he still made the same statement; but when five grammes more were added, he recognised the right as the heavier. With the left foot he recognised a difference in weight of one or two grammes, when there was already a weight

of five grammes in the bag, but not otherwise. With the right foot, he readily perceived a difference of two grammes.

He walked with the aid of a stick, and when in his house did not even use this; he said that he felt no fatigue in walking, and could stand several hours daily.

In commenting on this case, Dr. Burresi remarks that recovery was much more complete than in another case of division of the spinal cord on the right side, which he described in *Lo Sperimentale* in 1871. He has recently examined the patient, six years after the injury. The right lower limb is much less nourished than the right; the circumference of the left thigh at its middle is four centimètres more than that of the right, and the left calf measures two centimètres more than the right. When he lies on his back, he cannot raise the right leg vertically to the long axis of the body. The left leg is raised with great ease and energy, and can be placed at right angles with the body. The patient can walk considerable distances, but the right foot is always moved like a scythe (*mosso a falce*).

Sensibility to pain and thoracic sensibility are completely lost in the left leg and foot; pricking with a pin produces only tactile sensation, and the temperature of hot or cold water is not perceived. Tactile and local sensibility, and sensibility to tickling, are normal in the whole left lower limb; in the right, sensibility is normal in all forms, that of pain being perhaps a little exaggerated. The man has a constant sensation of cold in the right foot, especially in winter; the skin has the same colour in both feet; the right perspires rarely even in summer, and always much less than the left. To the touch the right foot feels much colder than the left; the difference of temperature diminishes gradually up to the knee, beyond which point it is not perceptible. The temperature of the right foot is 85.1° Fahr., of the left 95° Fahr.

In both the patients there remains a slight degree of paralysis on the side of the injury, slight atrophy and very slight hyperæsthesia on the paralysed side; while on the non-paralysed side there is diminution of thermic sensibility, and of sensibility to pain in Lazzeri (the former patient), of muscular sensibility in Tanzi.

In some further remarks, Dr. Burresi refers to the letter addressed to him by Professor Schiff, and published in *Lo Sperimentale* last year (see LONDON MEDICAL RECORD, July and August, 1875). In compliance with Dr. Schiff's suggestion, he ascertained the temperature of the axillæ, hands, and feet, in Tanzi's case, by thermometric observations made twice or more frequently daily from May 11 to June 14. (A detailed table of the observations is here given; the summary of which is stated by Dr. Burresi as follows.)

The minima and maxima observed were:—

	Minimum.	Maximum.
Right axilla .	98.06° Fahr.	100.04° Fahr.
Left axilla .	97.16 "	100.04 "
Right foot .	73.04 "	98.60 "
Left foot .	73.40 "	98.24 "
Right hand .	90.00 "	100.04 "
Left hand .	93.56 "	100.04 "

On May 19–22 there was fever, and the temperature in the axillæ rose to 102.74° ; on these days only the temperature of the feet rose above 98.6° , reaching as high as 99.68° .

In both the lower limbs the oscillation of tempe-

rature did not bear a relation to the general temperature as measured in the axillæ, except on the days of fever. The minimum temperature in the feet (73.04° and 73.4° Fahr.) was observed on June 25, with a temperature in the axillæ of 98.6° and 98.7° Fahr., and the maximum (98.6° and 98.24° Fahr.) was observed with an axillary temperature of 99.32 on June 16, and of 99.68° Fahr. on May 26.

Neither did the oscillation of temperature in the upper limbs bear relation to the general temperature; the minimum of 90° and 93.56° Fahr. was observed on June 9, when the temperature in the axillæ was 99.5° and 99.68° Fahr.

The oscillation of temperature in the lower limbs was not alike in the two feet. Many times the right foot was warmer than the left, and on May 18 the temperatures were respectively 93.2° and 87.8° Fahr.; many times it was colder, and on May 1 the temperatures were 91.58° and 94.28° Fahr. respectively.

The oscillations of temperature in the upper limbs were not similar in the two hands. On many occasions the right hand was colder than the left, the temperatures on June 2 being, right, 90° , left, 93.56° . At other times the reverse was observed, and on June 2 the temperatures were 98.6° and 97.16° .

In seventy-three measurements the right foot was colder than the left thirty-four times, warmer thirty-two times, and of the same temperature seven times.

In twenty-six measurements the right hand was colder than the left twelve times, warmer four times, and of the same temperature ten times.

On twenty-six days on which two or more thermometric measurements were made, the right foot was warmer in the afternoon than in the forenoon twenty-six times, and the left foot twenty-one times.

On twelve days on which two or more measurements were made, each of the hands was on ten occasions warmer in the afternoon than in the morning.

The conclusions from these observations are these. 1. Oscillations of temperature in the limbs occurred independently of the general temperature of the body. 2. These oscillations were observed in both upper and lower limbs, and on the non-paralysed as well as the paralysed side. 3. An increase of temperature in the limbs was observed much more frequently in the afternoon hours. 4. The temperature of the two lower limbs differed more frequently than that of the two upper limbs. 5. The temperature was greater in the non-paralysed as compared with the paralysed foot, rather more frequently than in the right hand as compared with the left. It may be inferred that more than one oscillation of temperature occurred in twenty-four hours. Thus, on May 14, at 4 A.M., the temperature of the right foot was 97.52° ; at 8.30 A.M., 83.48° ; at 1.30 P.M., 95.36° ; and at 6.30 P.M., 97.52° . Several times the temperature of the limbs in the morning was higher than at noon, and there was again a rise in the evening.

CHARCOT ON THE LOCALISATION OF CEREBRAL DISEASES.

(Continued from page 98.)

Before entering upon a description of these vessels, it is necessary to investigate more closely than has yet been done, in this course, the parts to which they are distributed. It concerns indeed parts of the brain of extreme interest in relation to the theory of cerebral localisations, to wit, the optic thalamus, the

nucleus caudatus, the nucleus lenticularis, and the capsula interna, which united may be called the *central system*, in contradistinction to the *cortical system*.

The lecturer recalls how the cerebral peduncle, rounded at the moment where it reaches the optic thalamus, flattens out after it has passed therein and enlarges from before backwards like a fan. Upon this fan nuclei of grey matter are disposed thus: posteriorly and to the inner side the optic thalamus; within this, but above and in front of it, the nucleus caudatus. On the outer side of the fan, and below the optic thalamus and the nucleus caudatus, is situated the nucleus lenticularis, which extends anteriorly nearly as far as the head of the corpus striatum, and behind as far as the posterior extremity of the optic thalamus. He describes shortly the form and relations of these grey masses, thus. First, the optic thalamus has the aspect of a flattened ovoid; the superior surface looks towards the lateral ventricle, and the inferior, which is also internal to the middle ventricle. It is with difficulty separated by dissection from the neighbouring parts. Second, the nucleus caudatus has the form of a comma or a pyramid, of which the thick end is directed anteriorly and to the inside, and the tail above and to the outside. The superior surface projects into the ventricle while the artificial inner surface is in its greater part applied to the upper extremity of the capsula interna. It is easy to isolate by dissection, but to do so we must cut through the numerous fibres it receives from the capsula interna. Third, the nucleus lenticularis, although covered on its whole surface, may be easily isolated; its form is that of an ovoid with one extremity anterior and the other posterior. It is divided into two parts: *a*. the anterior third, constituted by a uniform mass of grey matter, is confounded in its anterior extremity with the intraventricular nucleus; *b*. the second portion, which corresponds to the two posterior thirds, is flattened from above downwards, so as to present an angle within towards the capsula interna. The inner and superior surface is intimately united to the capsula interna, and the under surface is parallel to the base of the brain. The external surface is in relation to the capsula externa, and beyond that with the nucleus tæniæformis and the island of Reil. In a hardened preparation, it is easy to separate the capsula externa from this outer surface, on account of the absence of medullary fibres or vessels passing from one to the other. The capsula interna is in part at least the prolongation not of the whole cerebral peduncle, but of the basis or crust, the tegmentum becoming connected with the corpora quadrigemina and the optic thalamus, and not taking part in the formation of the capsula interna. It was formerly held that the capsula interna was an immediate and complete emanation from the base of the peduncle. This has been disproved by MM. Luys and Kölliker, but these authors have gone too far in stating that the capsula interna is formed entirely of fibres of the corona radiata, which terminate in the ganglia, and of fibres which, leaving the ganglia, expand in the corona radiata; for MM. Meynert, Henle, and Broadbent, are of opinion that there exists a third order of directly continuous fibres which pass from the crust to the grey matter of the hemispheres. The reality of their existence depends upon a certain number of pathological proofs, such as the cases of descending degeneration observed by M. Vulpian and the lecturer, in which yellow softening, having

destroyed in a great extent the median convolutions, without concomitant alterations of the corpus striatum, gave rise to a degeneration which could be followed right down as far as the lower part of the cord. He thinks that of these fibres those anterior are centrifugal, and connected with the movements of the limbs, while those posterior are for the transmission of accessory impressions. In short, the capsula interna is thus constituted: 1. By direct peduncular bundles which pass through it without stopping in the ganglia; 2. By indirect peduncular bundles, some of which pass to the corpus striatum, reaching it by its under surface, while others go to the nucleus lenticularis, which they penetrate by its first segment. They are very numerous in this segment, but become less and less so in the second and third, to which inequality is due the difference in colour of these three segments. To these bundles, which from the base of the peduncle pass to the central grey ganglia, certain bundles succeed in the upper part of the capsula interna, which, taking origin in the ganglia, go to take part in the formation of the corona radiata, and direct themselves towards the cortical grey matter. These bundles are called radiating bundles, and must be distinguished as (1) those that come from the corpus striatum; (2) those from the optic thalamus; (3) those from the nucleus lenticularis, which arise principally from the upper edge of the second and third segments. It follows, therefore, that four orders of bundles enter into the composition of the corona radiata, and connect the capsula interna with the cortex of the brain. These are:

1. The bundles from the optic thalamus.
2. Those from the corpus striatum.
3. Those from the nucleus lenticularis.
4. Those direct from the base of the peduncle.

The lecturer goes on to describe the arterial circulation in the central ganglia, under this name designating the thalami optici, the corpora striata, and their annexes. He points out that in this position the vascular system is of great pathological importance, for not only have we the ischæmic alterations met with in the cortex, but also hæmorrhages, rarely met with in the latter situation. According to the statistics collected by Andral and Durand-Fardel, in 199 cases of hæmorrhage, the optic thalami and corpora striata were the seat of rupture in 102, and only seventeen times did the extravasation originate in any other part of the brain; on the other hand, ischæmic alterations, according to Durand-Fardel, are much more common at the periphery, and the lecturer's own observations at the Salpêtrière confirm this statement. He points out that, if the study of the cortical arteries is a necessary introduction to the consideration of ischæmic softening, so in like manner the present details are indispensably preliminary to the history of intracerebral hæmorrhage.

He proceeds to recall to his hearers that the arterioles which constitute the central system are derived from each of the three great arterial trunks in the immediate neighbourhood of their origin from the circle of Willis; those for the corpus striatum are arterioles of half a millimetre to a millimetre and a-half in diameter, according to M. Duret. Their direction is perpendicular, and, borrowing Heubner's simile, they resemble the straight shoots at the base of a forest tree; in their perpendicular course they resemble the arteries of the cortex, but these latter are according to Robin's definition capillaries, not arterioles. Moreover, the central arteries have another

character which distinguishes them very plainly from the cortical vessels, namely, they are 'terminal arteries'; that is, they terminate in pencil-like tufts of capillaries, not anastomosing with neighbouring vessels, and not communicating in any way with the territory of the cortical arteries; whichever way injections are made, no communication can be demonstrated. He directs attention to the analogous arrangement in the pons, the median arteries passing backwards without anastomosing; and in the medulla the same disposition exists, modified by the fact that the arteries there arise, not from the vertebral trunks, but from the spinal arteries. The lecturer thinks it possible to find in the mode of origin and distribution of these arteries a mechanical explanation of the frequent occurrence of rupture in these parts; thus on the surface of the hemispheres, where hæmorrhages are comparatively rare, the arteries do not pierce the brain-substance until after a long course in the pia mater, and till after they are transformed into very slender vessels, properly speaking, capillaries; on the other hand, the road from the heart to the great ganglia at the base is very short. The arteries distributed to them are almost directly derived from the arteries of the circle of Willis, a circumstance extremely favourable to their rupture, though compensated for in some measure by their course being at right angles to that of the parent stems, and also by the difference in calibre. Compared with the cortical arteries they are very voluminous, especially the arteries of the corpus striatum; and, lastly, the absence of anastomoses does not allow the collateral circulation to relieve excessive pressure in any given vessel:—

The three great arterial trunks all take part in the supply of these ganglia, but their share is very unequal; the anterior cerebral takes the least, next the posterior cerebral, and of all the Sylvian artery is the most important; this therefore will be taken as the type for description. The following is their distribution.

(a) The Sylvian artery supplies the greater part of the nucleus caudatus, the whole of the nucleus lenticularis, a part of the optic thalamus, and the whole extent of the internal capsule.

(b) The anterior cerebral artery only supplies, and that not constantly, the anterior extremity of the nucleus caudatus.

(c) The posterior cerebral artery, besides furnishing branches to the choroid plexuses and the inner surface of the ventricles, supplies the inner and posterior part of the optic thalamus, the corpora quadrigemina, and the tegmentum.

It is necessary to develop still farther the description of the arteries of the corpus striatum; afterwards the necessary facts relative to the central vessels derived from the anterior and posterior cerebral arteries will be briefly related. In order to follow these branches after they have pierced the brain-substance at the locus perforatus anticus, a dissection must be made, and the grey matter of the island of Reil, the subjacent white matter, the nucleus tæniæformis, and the capsula interna must be removed, thus laying bare the external surface of the nucleus lenticularis in its whole length, and now we can follow the distribution of the principal arteries of the corpus striatum. We see that they are arranged like a fan on the surface of the grey matter, but they soon pierce its substance, and are lost to view. The ultimate distribution of these arteries can only be followed by making transverse

sections. A first section made posterior to the optic chiasma shows only the nucleus caudatus and the nucleus lenticularis, the optic thalamus being more posterior. The arteries just now lost sight of reappear here in their deep course; moreover, other still smaller arterioles are visible on the external surface of the nucleus lenticularis, which may be called the inner group. These, after springing from the Sylvian trunk, rise almost perpendicularly in the two first segments of the nucleus lenticularis and in the contiguous parts of the capsula interna. The external group is yet more interesting; they may be divided into two groups, the first, anterior or arteriæ lenticulo-striatæ, the second, posterior or arteriæ lenticulo-opticæ. One of the arteries of the anterior group is above all important on account of its size and the part it plays in intracerebral hæmorrhage. After having penetrated the third segment, it traverses the superior part of the capsula interna, then reaches the thickness of the nucleus caudatus, and continues right up to the most anterior extremity of this ganglion, passing from before backwards. The study of this artery ought to be made on sections anterior to that described above. The posterior group are disposed on the same model, only, after having crossed the most posterior part of the capsula interna, they reach the outer and anterior extremity of the optic thalamus, where they are distributed. He repeats that we have here to do with *terminal arteries*; and that, if the injections be made too forcibly little eruptions will take place, imitating, by their seat and their form, the hæmorrhagic extravasations which we meet with in pathological conditions. As to the branches of the anterior cerebral, all that need be said is that they can give rise to very circumscribed hæmorrhages, but which may have real gravity, as they frequently open into the ventricles. The posterior cerebral artery deserves more minute attention. We need, however, only refer to the branches sent by it to the optic thalami. These are of two orders; the first, the posterior internal optic artery, supplies the inner surface of the optic thalamus, and is capable of giving rise to hæmorrhages serious from the frequency of extravasation into the ventricles; the second, the posterior external optic artery, traverses part of the cerebral peduncle before entering the hinder part of the optic thalamus; rupture of this artery causes hæmorrhages which frequently are poured out into the substance of the cerebral peduncle. Having collected these facts, highly interesting in their relation to the theory of pathological cerebral localisations, it is necessary to examine them a little more closely, commencing with those which concern the central ganglia.

(A.—a.) The whole system of central arteries derived from the Sylvian may be obliterated by embolism or thrombosis of the main trunk. Then the softening affects almost the whole mass of the central ganglia, only those parts supplied by the anterior cerebral and optic arteries remaining intact. We have there a very summary localisation, in general of extreme gravity, and which epitomises, so to speak, clinically, all the pathology of the ganglionic centres. The symptoms connected with this softening are no others than those of common cerebral hemiplegia, with accompanying cerebral hemianæsthesia.

(b) Analysis can penetrate into this complex association. It is not, however, right to believe that we are in a position, for the present, to recognise by particular symptoms the destruction of the nucleus.

caudatus, of the optic thalamus, of the nucleus lenticularis, or *à fortiori*, of their different segments.

(c) It is possible, notwithstanding, that we may, by means of the actual distribution just considered, recognise an anatomical localisation, susceptible of revealing itself by special symptoms and permitting, in consequence, a regional diagnosis. This condition is realised when the softening affects all or nearly all the extent of the parts supplied by either the anterior or posterior divisions of the external group of arteries derived from the middle cerebral. We see that the symptoms differ in the two cases; the symptoms of cerebral hemianæsthesia present in the one (when the posterior division is affected) are absent in the other.

(B.) That which has just been said of softening is also true of hæmorrhage. This is very frequent in this region, as these arteries are very subject to the form of sclerosis terminating in miliary aneurisms. We may commonly find in a hæmorrhagic extravasation an artery bearing little aneurisms on its prolongations.

Most commonly hæmorrhage takes place, not, as is usually believed, into the substance of the corpus striatum, but outside it, more precisely in contact with the external surface of the nucleus lenticularis, between this surface and the capsula externa. However, it must be noted that the interpretation of the signs of hæmorrhage presents difficulties which do not exist in the same degree in softening, on account of the compression to which neighbouring parts are subjected by the effused blood.

It is possible to reduce to a very small number of propositions the facts definitely acquired relative to the regional diagnosis of the different parts which enter into the composition of the central ganglionic masses.

1. We are not in a position to recognise isolated lesions of each of the nuclei without participation of the capsula interna. Thus we cannot distinguish during life a limited lesion of the nucleus lenticularis from a circumscribed lesion of the nucleus caudatus; and the lesions of the optic thalamus, —though on this point some reserves may be made— are confounded with those occurring in the two compartments of the corpus striatum.

The symptoms which accompany these lesions, limited to the grey masses, are those of common cerebral hemiplegia. This form of cerebral hemiplegia may be called cerebral, to distinguish it from those motor paralyses resulting sometimes from a lesion of certain superficial regions, and which by opposition the lecturer proposes to call cortical cerebral hemiplegias.

2. In the majority of cases the paralysis due to a lesion of these central ganglia affects movement only, the disturbances of sensibility occurring only under certain circumstances hereafter to be considered.

3. Hemiplegia connected with lesions so circumscribed within the grey masses is commonly transitory, not well marked, not irrecoverable, and comparatively benign. In formulating this proposition, it is obvious that it does not include cases in which serious complications occur, such as hæmorrhage into a ventricular cavity; for in such a case grave symptoms, early contraction, and epileptiform convulsions supervene, and death, more or less rapid, is the almost necessary consequence. This benignity is due to the fact that in such cases the ganglia are not entirely destroyed; for instance,

the nucleus caudatus is never entirely destroyed, at least by itself, without participation of the capsula interna or other grey masses. On the other hand, the transitory character of these paralyses ought to indicate a functional supplementation between different ganglia and between different parts of the same ganglion.

In opposition to this benignity, the lesions of the capsula interna, even when they are limited to the white matter and do not affect the grey masses at all, produce common cerebral hemiplegia, in a form generally very well marked and more or less persistent. Thus, even when well circumscribed, principally when situated low down on the side of the peduncle, these lesions determine a motor paralysis, which is accompanied almost necessarily by late contractions—a symptom of bad omen, as a rule announcing that the paralysis will resist all therapeutic means.

The symptoms vary according to the seat of the lesion in the capsula interna; if the anterior two-thirds, the parts supplied by the lenticulo-striate artery, be alone affected, the paralysis will be simply motor; if on the other hand the posterior third, supplied by the lenticulo-optic arteries, be destroyed, then hemianæsthesia follows as a necessary consequence. Most often, the lesion being seated in mixed territory, both phenomena are present.

In the preceding exposition the lecturer has only alluded to *destructive* lesions of the capsula interna, which produce in this tract an irreparable loss of substance; these must be distinguished from those which affect the capsula interna only by contiguity, being themselves limited to the ganglionic masses which surround it. Thus the distension of one of these ganglia by a hæmorrhage would cause compression of part of the capsula interna and a suspension of the function of the fibres compressed, but, as the fibres would be only compressed, not destroyed, on the removal of the pressure by reabsorption of the clot or otherwise the paralysis would disappear. Such a state of things is of frequent occurrence clinically, and has led to errors in the interpretation of symptoms, as it has been usual to ascribe to the destruction of these ganglia symptoms which were purely owing to the compression of parts of the capsula interna. Supposing the case of a hæmorrhage at the seat of election, that is, just on the outer surface of the third segment of the nucleus lenticularis. On the outer side of the lesion the convolutions of the island of Reil, the nucleus tæniæformis, and the capsula externa, resist the efforts of the effused blood, while the ganglia are pushed towards the ventricular cavities. Whilst the hæmorrhage remains limited to the anterior two-thirds of the nucleus lenticularis, the corresponding portion of the capsula interna alone will be affected; but as, little by little, the effusion extends from before backwards, so as to involve the posterior part, the hinder portion of the capsula interna will in like manner become compressed, and hemianæsthesia will be superadded to the already existing hemiplegia. When, therefore, on the one hand, hemiplegia is found associated with a lesion of the corpus striatum or hemianæsthesia, with injury of the optic thalamus, we must not conclude, as many authors have done, that these are centres either of motility or common sensibility, but that the phenomena are simply the results of compression of certain bundles of the capsula interna. For, if the patients survive, the symptoms disappear; and, on examining the brain, only a linear ochreous cicatrix

in the ganglia is left to mark the site of the former hæmorrhage.

In order to support what has gone before and to prepare his hearers for further investigations, the lecturer proceeds to recall certain details relative to the anatomy of the capsula interna. Following Meynert, he makes the following dissection. Having opened the lateral ventricles, he removes successively the tegmentum or superior layer of the peduncle, the corpora quadrigemina, and the entire optic thalamus; this being done, there are exposed to view the crust or under layer of the peduncle, and higher up the peduncular fibres passing to the nucleus caudatus. The fibres belonging to the nucleus lenticularis occupy a place situated below and external to the preceding. On observing the innermost and hindmost part of the fan formed by the peduncular fibres here exposed, a bundle can be distinguished detached from the rest, and which, without penetrating the grey masses, curves backwards at the point where it reaches the inferior border of the nucleus lenticularis. This is a direct bundle, which passes to the corona radialis without stopping in the grey matter of the central ganglia. The course of this bundle has been followed by M. Meynert in the brains of monkeys, and he finds that it passes into the white substance of the occipital lobe just outside the posterior cornu, and terminates in the grey matter of that lobe. It passes downwards as far as the pons Varolii in the lower layer of the peduncle, where it occupies the most external part; having reached the pons Varolii, it is found to lie in the posterior part of the pyramidal bundle, and keeps the same position in the anterior pyramid itself as far as the decussation, after which it goes to join the posterior spinal bundles. Such are the facts, according to M. Meynert; but, interesting though they be, they are not of themselves sufficient to explain the problems which occupy us, and the lecturer takes this opportunity of repeating that physiology and pathology cannot be deduced from the facts of anatomy alone. It is therefore important to add to these certain clinical and anatomopathological proofs, especially the observations of MM. Türk, Rosenthal, Veyssière, and Rendu. He says that it is the unanimous result of the concurrence and comparison of these observations, that lesions affecting the posterior lenticulo-optic region of the capsula interna, have for their necessary consequence, that form of hemianæsthesia which is called cerebral, and in which the senses presided over by the cerebral nerves properly so-called, the optic and olfactory nerves, are implicated in a manner to reproduce faithfully the characters of hysterical hemianæsthesia, and that on the contrary in all the cases where, this region being preserved, the lesion affects only that part of the capsula contained in the nucleus lenticularis and the head of the nucleus caudatus, anæsthesia is absent. The clinical data which are of such incontestable importance are supported by the direct experiments of MM. Veyssière and Duret, who found by making limited lesions of the central parts of the brain by means of a spring trochar, that when the posterior part of the capsula interna was destroyed, hemianæsthesia of the opposite side of the body inevitably occurred, and was often accompanied by a slight degree of motor paralysis, which latter phenomenon was alone present without accompanying anæsthesia when the lesion affected only some part of the two anterior thirds of the capsula. All, there-

fore, concurs to prove that in the posterior part of the capsula interna there are centripetal fibres serving to carry sensory impressions from the periphery of the opposite side of the body to the cortical grey matter. These fibres pass direct to take part in the formation of the corona radiata. Near their origin these fibres being, as it were, gathered together, and comprised in a very limited space, produce, if injured, very extensive anæsthesia; but higher up, where they are spread out, a similar lesion produces much less pronounced effects, and this is not a mere *à priori* truth, but a well-established clinical fact. It is important to ascertain whether a lesion of the occipital lobes also determines crossed hemianæsthesia. Unfortunately, information on this head is not sufficiently explicit, and the point must be reserved. Nevertheless, it is necessary to notice that the fibres which compose the posterior part of the capsula interna, and their emanations, cannot be considered as a centre of sensorial or sensitive impressions. These bundles can only be considered as a place in which all the centripetal fibres are found represented before diverging towards the superficial parts of the brain.

In his observations on hemianæsthesia, M. Charcot endeavoured to show that it is a consequence of lesions of the posterior part of the capsula interna or its expansion in the corona radialis, and the action of these lesions may be either destructive or compressive, or perhaps suspensive; he reserves to himself the determination of the value of the latter term. For the purpose of bringing more into relief certain points hitherto left in the background, he refers briefly to the characteristics of the disease, which he names cerebral hemianæsthesia to distinguish it from all other forms of deadening or suppression of sensibility which do not owe their origin to a brain-lesion. This disease presents characters exactly similar to hysterical anæsthesia, which is by far most commonly unilateral; the head, the limbs, the trunk on one side of the body are affected, and the functional derangement usually affects the sense of touch, pain, and temperature, the electro-sensibility of the muscles not sparing even the mucous membranes. It is important to notice that it is not only common sensibility that is affected, but also the special senses, not only those whose nerves emanate from the medulla, as the senses of taste and hearing, but also those of sight and smell, whose origin is from the brain proper. Taking as an example the affections of sight, the lecturer points out that hysterical amblyopia differs in no respect from the crossed cerebral amblyopia due to organic disease. Taking first the case of hysterical amblyopia we find: 1. The more or less pronounced diminution, or which is much more rare, absolute loss of sight in the eye of the side corresponding to the hemianæsthesia. 2. There exists in the fundus of the eye no alteration visible by the ophthalmoscope, no difference of vascularity between the two eyes. 3. Acuteness of sight is frequently diminished by one-half or altogether. 4. There exists a concentric and general reduction of the field of vision. 5. Lastly, the peculiar general and concentric reduction of the field of vision for colours merits slight attention. He recalls to the minds of his hearers that, in the normal condition, the retina is not throughout equally sensitive to different colours; that for blue the field of vision is largest, next for yellow, then orange, red and green, while lastly, violet is perceived only by the most central part of the retina. In the pathological

condition now under consideration, this normal physiological condition is exaggerated and the chromatic circles are concentrically reduced in a more or less marked manner following the physiological law. The circle of violet may be reduced to nothing, and the disease progressing, violet, red, and orange will follow in turn, yellow and blue persisting to the last, until all colours are finally imperceptible, and the patient sees all objects of a neutral or sepia tint. Such are the phenomena, which the lecturer has many times demonstrated in hysterical patients, and they are found constantly in many cases of cerebral amblyopia, accompanied by hemianæsthesia, and due to a localised lesion of the brain. He would insist particularly on the absence of ophthalmoscopic changes, which permit us to separate this disease from those in which neuro-retinitis and choked disc are easily recognisable. The fact that the localised lesions of the brain which cause hemianæsthesia cause in consequence crossed amblyopia, is of immense importance to the theory of cerebral localisations. It is known that, according to the theory of Von Graefe and to the recently published work of Dr. Schoen, such cerebral lesions cause suppression of the right or left half of the field of vision according to the side of the lesion. M. Charcot considers this view of Von Graefe's too absolute, and would formulate in opposition the following theory; 'the lesions of the cerebral hemispheres which produce hemianæsthesia, determine equally crossed amblyopia and not lateral hemiopia.' He is not in a position to deny that lateral hemiopia is due to some localised lesion of the brain, but is inclined to the opinion, that when this phenomena exists it is rather the result of contiguity, and the implication of the optic tracts. He considers this a proper place for some details relative to hemiopia and the presumed anatomical cause of its development. He refers to the anatomical hypothesis of a semi-decussation in the optic commissure, which was emitted first by Newton in his *Treatise on Optics*, 1704. This theory consists in supposing that the external nerve-tubes on each side pass direct to the respective eyes, while those on the inner cross in the commissure. This theory does sufficiently explain lesions of the optic tracts, the commissure and nerves, but not the lesions beyond the corpora geniculata. There is not a single observation in support of such a view; and moreover, modifying a little further the above anatomical hypothesis, and assuming that those tubes which decussate in the chiasma reach their deep origin without further decussation, while those which pass direct to the retina undergo in the deep parts of the brain, possibly the corpora quadrigemina, a complete decussation, there would result a re-union of the tubes supplying the whole of each retina at some given point in the depth of the brain-substance, so that, while a lesion of the tract or the nerves would produce a lateral hemiopia, on the other hand a lesion situated in the substance of the hemisphere would produce crossed amblyopia. He then proceeds to inquire whether crossed amblyopia is an habitual accompaniment of hemianæsthesia, resulting from a lesion of the capsula interna. This hemianæsthesia of common sensibility finds its explanation in the existence of a bundle of direct centrifugal fibres, that is to say, fibres which do not stop in the central ganglia, and which, at the exit of the capsula interna, form the most posterior part of the base of the corona radialis. He asks whether any connection exists between this bundle and those sensorial fibres,

destined to form the communication between the visual apparatus and the cortex of the brain, and in order to answer this question, he considers it necessary to first study the deep origins of the optic nerves. If we study the anatomy of the corona radialis by removing the superior parts of the hemispheres, so as to lay bare the ventricular cavities, and detach the nucleus caudatus with its corresponding radiating fibres, the cortico-optic radiating fibres may be seen. These may be divided into three groups: some pass towards the frontal regions; others direct themselves mesially or laterally; others again going posteriorly are designated, after Gratiolet, who first studied them, cerebral expansions of the optic nerves. This last group, the especial objects of our study, are only separated from the posterior cornu by the ependyma and the tapetum.

It is in this very region, but in a deeper plane, that are distributed the cerebral expansions of those centrifugal fibres, lesions of which cause hemianæsthesia of cerebral origin. There is, therefore, a relation of contiguity between these bundles and the optic expansions which can give an anatomical explanation of the frequent co-existence of hemianæsthesia and crossed amblyopia, if it can be established that these expansions are really a more or less direct prolongation of the optic nerves. In order to examine this last point, it is necessary to consider what we already know relative to the origin of the optic nerves. We know that behind the optic commissure, the optic nerves are called the optic tracts, and are divided into two portions, internal and external. The external portion, following the researches of MM. Meynert, Huguenin, and others, takes its origin in three nuclei of grey matter, namely, the optic thalamus, the external corpus geniculatum, and the nates. This origin received some support from the experiments of M. Gudden, who having extirpated the eyes of very young rabbits, killed them after several months, and found that atrophy had extended to the nates, the optic thalami, and the external corpora geniculata, while the testes and the internal corpora geniculata were intact. The internal portion passes manifestly into connection with the corpus geniculatum internum, and traversing this terminates in the nates. According to M. Huguenin, this internal portion in men, at least, is in direct anatomical relation with the testes. In a recent case of an ataxic woman, who had been blind for fifteen years, the grey induration of the optic nerves was followed as far as the corpora geniculata; the nates and testes had preserved their normal colour, but were much reduced in size.

It is necessary to follow the connections of the centres just enumerated with the grey cortex of the brain. These connections are in fact formed by a system of fibres, which constitutes the most posterior part of the radiations of the optic thalamus, and which are sometimes called the optic radiations of Gratiolet. The anatomical details relative to this point may be followed in a plate borrowed from M. Meynert. Bundles from each of these centres pass to join the direct peduncular fibres. In this collection of fibres are found mingled without doubt fibres from the olfactory tract, and clinical facts indicate also the mingling of fibres connected with the auditory and gustatory nerves. If this at present hypothetical arrangement should be verified anatomically, it would explain the occurrence of crossed interference with smell, taste, and hearing, which are habitually phenomena of cerebral hemianæsthesia. The next

question he sets himself to solve is, whether there are any facts in support of his hypothesis of a deep decussation of the direct fibres (those that do not cross in the chiasma) of the optic nerves. He says that the subject presents extreme difficulty in a purely anatomical point of view. From the preceding description it may be seen that the only point in which the bundles approach the middle line of the brain in their deep course is in the corpora quadrigemina, and here, although without doubt numerous crossing fibres may be demonstrated, it is impossible to prove that they are continuous with the optic nerve-fibres, more especially that they are continuous with the direct fibres of those nerves. Flourens proved by experiment that ablation of the optic tubercles caused crossed amblyopia in mammals and birds, but these animals were those having eyes directed outwards, and in which the decussation in the chiasma is without doubt complete. In man, the proof is yet wanting. He quotes, however, an observation of Dr. Bastian's, in which case an unilateral lesion of the testes produced cross amblyopia, but considers the question too delicate to be decided by this single case.

He next passes to consider whether crossed amblyopia is the only functional derangement of vision in brain-lesions, or whether hemiopia does ever occur under these circumstances. He is inclined to think that in the reported cases, the lesion, being in the lower part of the brain, has implicated the optic nerves themselves. He admits that there are certain cases in which right-sided hemiopia is complicated with aphasia and right side paralysis, and cases in which it is the consequence or accompaniment of migraine, which are not explained by this hypothesis.

(To be continued.)

ANATOMY AND PHYSIOLOGY.

CUNNINGHAM ON THE BRONCHO-ŒSOPHAGEAL AND PLEURO-ŒSOPHAGEAL MUSCLES.—In the *Journal of Anatomy and Physiology*, for January, 1876, Dr. Cunningham fully describes the position, relations, and probable function of the broncho-œsophageal and pleuro-œsophageal muscles. Professor Hyrtl was the first to describe them, in the year 1844, and two years later Sir J. Paget confirmed the discovery; but ever since then the existence of these muscles has been well-nigh ignored, being either not mentioned at all in most anatomical works, or else dismissed after a very transient notice. [Meckel, in his *System der vergleichenden Anatomie*, makes no mention of these muscles.—*Rep.*] About nine months ago Dr. Cunningham's attention was directed to them by a student, and since that time he has made fourteen dissections of these muscles.

In all of these cases, one excepted, the pleuro-œsophageal muscle was present, while in ten cases both muscles were seen. The exceptional case, in which neither muscle could be found, was that of an old cripple, most of whose extremities had been paralysed for several years, and the muscular tissue of whose œsophagus was very pale and loaded with connective tissue.

1. *The Pleuro-œsophageal Muscle.*—After two flaps, made by cutting longitudinally through the posterior wall of the pericardium, have been turned to each side, this muscle, in the shape of a thin slip about one inch and a half long, and from a

quarter to half an inch broad, will be seen rising from the left pleura, passing over the thoracic aorta, and forming the left boundary of the posterior mediastinum. Thence, after arching over the aorta, it enters the left margin of the œsophagus, its fibres diverging, a few upward, but most downward, to the stomach. Instead of only one, there is sometimes a second, or a third, or even six muscular slips. When one alone is present, its position corresponds with the eighth dorsal vertebra.

2. *The Broncho-œsophageal Muscle.*—A deeper dissection is required to expose this. After removal of the left lung by cutting through the bronchus as it enters the organ, and gently drawing forward the cut extremity of the former by a hook, the muscle will be seen in the loose tissue between this tube and the gullet. This is never so well marked as the muscle first described. In the shape, generally, of two slips with a circumference no greater than whipcord, its fibres, expanding as they pass downward and backward, mingle, at a point a little above the pleuro-œsophageal muscle, with the anterior longitudinal fibres of the gullet. Besides these two muscles, the œsophagus has sometimes yet other, but less constant, muscular connections with the walls of the posterior mediastinum.

None of the theories regarding the function of the two muscles are satisfactory. According to Hyrtl they act together—the broncho-œsophageal pulling the posterior wall of the bronchus outwards, while the pleuro-œsophageal holds the œsophagus downward. The occasional absence of the former slip, however, negated this view. Henle was of opinion that they protect the arteries from pressure and friction, the broncho-œsophageal, during the act of swallowing, drawing the gullet forward, and thus moderating the pressure of the bolus of food upon the bronchial artery. The only conclusion at which Dr. Cunningham can arrive, after much thought, is 'that these muscles, by their attachments, serve to give the œsophagus fixed points upon which it can contract the more readily in the process of swallowing.' They may also take some part in restoring the gullet to its right position, after each descent which it makes with the diaphragm in inspiration.

J. C. GALTON.

MARKWALD ON DIGESTION AND ABSORPTION IN THE LARGE INTESTINE IN MAN.—The investigations of M. Markwald (*Virchow's Archiv*, vol. lxiv. p. 505, and *Centralblatt für die Medicinischen Wissenschaften*, no. 7, 1876), relate to a case of preternatural anus, in consequence of a piece of bowel at the junction of the cæcum and ascending colon becoming gangrenous in a case of strangulated hernia. The aperture of entrance into the large intestine was completely separated from the aperture of exit in the small intestine; the mucous membrane of the large intestine was quite normal. The small intestine was throughout its entire extent capable of being experimented upon. The temperature of the large intestine was 37·6° Cent. (99·7° Fahr.); the peristaltic action was very regular. The patient was forty-nine years of age, delicately built, but in good health.

(a) *On the Sugar-forming Ferment of the Large Intestine.*—Pieces of sponge were attached to strings and introduced into the upper end of the large intestine and left therein for two hours. During this time they had proceeded from 6 to 10 inches along the canal. The intestinal juice obtained by squeez-

ing the sponges was a somewhat sticky, turbid fluid, with a strong alkaline reaction, and containing a small quantity of albumen. When mixed with starch mucilage and kept at 40° Cent. (104° Fahr.) no sugar or at most only a trace was formed. Starch-mucilage enclosed in bags of muslin and placed in the large intestine, even after from four to six hours, showed no trace of sugar.

(b) *Digestive Experiments.*—1. Fibrin was introduced into the large intestine, partly free and partly enclosed in bags, some of which remained for twenty days in the intestine. The quantity of fibrin diminished considerably. The decomposition products found in the contents of the intestine were peptones, tyrosin, and indol, and the whole mass was penetrated by bacteria. The author regards the whole process as one of decomposition. Eighty-four per cent. of a quantity of fibrin introduced into the large intestine and left there for twenty-six hours, was dissolved. 2. Coagulated egg-albumen also diminished considerably in weight. The decrease in weight did not increase proportionately with the time. The loss in twenty-four hours was 54 per cent.; after forty-six, 60 per cent.; and after seventy-two hours, 55·2 per cent. The products were the same as in the case of fibrin. If a large quantity of albumen, e.g. 181,818 grammes, were introduced, the diminution in the weight was not so large; in the case cited it only reached 30·4 per cent. The author sought to determine the absorption of albumen by estimating the quantity of nitrogen in the urine. Only in one experiment was there an increase of nitrogen in the urine, the patient being previously in a state of nitrogen equilibrium. The result of the experiments, the late absorption, seems to show that the case is rather one of decomposition than of normal digestion.

(c) *Absorptive Experiments.*—1. Water was absorbed from the large intestine only slowly. For the absorption of 250 cubic centimetres of water at least twelve hours were necessary. 2. Solutions of peptones. The patient was again in a state of nitrogen equilibrium; the increase of nitrogen in the urine after the introduction of the peptones ought to indicate the amount of absorption. The peptones were prepared from fibrin. In two experiments the solutions of peptones introduced proved powerful irritants, excited violent peristalsis, and no absorption was detected. 3. Equally negative results were obtained in four experiments with fluid egg-albumen, partly pure, and partly mixed with chloride of sodium. Regarding the normal process, the author concludes that the absorption from the large intestine goes on slowly, and only when a small quantity of water is present. Water is chiefly absorbed; peptones, when they are present in small quantity in the large intestine; in large amount, they excite the intestine and cause diarrhoea. Fluid albumen is not absorbed. That the function of the large intestine can be dispensed with without any material disturbance of the health is proved by the present case, the patient feeling quite well two and a half years after the formation of the fistula. Lastly, the author details an operative procedure for the performance of a fistula of the small intestine in the dog, just above the ileo-cæcal valve. Of the various preparations for the artificial nourishment *per anum*, the author prefers the flesh-pancreas clyster.

NAWROCKI ON THE INFLUENCE OF THE BLOOD-PRESSURE ON THE FREQUENCY OF THE HEART-

BEATS.—F. Nawrocki (*Beiträge zur Anat. und Phys. als Festgabe für C. Ludwig gewidmet*, p. 205, and *Centralblatt für die Medicinischen Wissenschaften*, no. 4, 1876), as the result of his investigations upon the above subject, finds that, when all the nerves which pass to the heart are divided, the frequency of the pulse is independent of changes of the blood-pressure (agreeing with the results of Knoll and Worm Müller). On the contrary, the force of the individual systoles increases with the increase in the blood-pressure. With intact vagi, Nawrocki, like Bernstein, Asp, and Knoll, found that the frequency of the heart-beats was diminished as soon as the pressure was increased, and accelerated when the blood-pressure was diminished. In all these experiments it is immaterial, as far as regards the frequency whether the accelerating nerves are intact or not.

In order to avoid as far as possible the irregularities which often occur in these experiments, the author made a very large number of experiments—about 400—on dogs, cats, and rabbits.

The experiments may be divided into three series: 1. Experiments with the heart completely removed from external nervous influences; spinal cord, vagi, depressors, and cervical sympathetic divided. (The section of the cervical sympathetic, according to Nawrocki, is unnecessary, in as far as he states that this nerve does not contain any fibres which either accelerate or regulate the heart.) 2. With the accelerator nerves intact; cervical spinal cord (and thoracic sympathetic) intact; vagi and dorsal spinal cord in one series, also intact; in another series divided. 3. With intact vagi: (a) on animals with intact nerves; (b) with exclusion of the accelerator nerves (section of the spinal cord). The increase of the blood-pressure was produced by compression of the aorta without opening the abdomen. (As in Stenson's experiment, a ligature is passed around the aorta from without, so that the vessel may be compressed against the spinal column.) Also by stimulation of sensory nerves; by transfusion of defibrinated blood from the same species. In experiments where the dorsal spinal cord was divided, an increase of the blood-pressure was obtained by electrical stimulation of the peripheral end of the cord. The diminution of the pressure was produced on the one hand by cessation of the above means of increasing the pressure; on the other, by stimulation of the depressor, section of the splanchnic nerves, and blood-letting.

VON WITTICH ON THE PHYSIOLOGY OF THE KIDNEY.—Von Wittich (*Arch. für Micros. Anat.* vol. xi., and *Centralblatt für die Medicinischen Wissenschaften*, no. 3, 1876) remarks that, if five cubic centimetres of a solution of ammoniacal carmine be injected into the jugular vein of a rabbit, death ensues in about fifteen minutes. If an examination be then made, not only the ureters, but generally the bladder also, are found to be filled with a red secretion. The microscopic examination of the preparation hardened in acidulated alcohol reveals the following appearances. The surface of the glomeruli is generally of a diffuse red colour, with irregular granular particles lying on them. There is no appearance of a more intense coloration of the nuclei of the vessels of the glomerulus, or of the layer of cells covering them. Between the glomeruli and the capsule there exists a colourless space. The epithelium of the capsule is not tinged. The lumina of the convoluted tubules are filled almost throughout their entire

length with masses of carmine, whilst the cells lining the tubules are always colourless. The straight tubules are generally filled with carmine. From these observations it appears (as was shown by Chrzonszczewsky), that the excretion of the carmine begins pretty regularly in the capsules of the glomeruli, and that then the excreted particles pass along the tubuli contorti into the tubuli recti without the gland-cells however being implicated in the process.

The author shows that, in from forty to fifty seconds after the injection of the carmine into the jugular vein, the first portion of the urine tinged with carmine passes from the pelvis of kidney into the ureter. In the rabbit, seven days elapse before the last traces of the five decigrammes of carmine injected are excreted by the kidneys. The same experiments performed on pigeons showed, without exception, accumulation of the carmine in the lumen of the tubules, whilst the accumulation of the urinary constituents proper, *i.e.* of the urates, takes place in the cells of the tubules.

There is therefore a remarkable difference in the relation of the kidneys to an ammoniacal solution of carmine and to sulphindigotate of soda; the latter, as was first shown by Heidenhain (LONDON MEDICAL RECORD, vol. i. p. 823), and confirmed by Von Wittich, being excreted by the cells of the convoluted tubules. Injection of these two substances simultaneously showed these differences most pronouncedly, although the author is unable to assign a reason for these appearances; nor did the introduction of these substances by the lungs serve to explain the result. Exactly the same results were obtained with the ammoniacal carmine as when it was injected into the blood directly; whilst the introduction of the indigo-carmine by the trachea was disadvantageous, in as far as this colouring matter could only be found in traces in the cells of the tubules.

In conclusion, the author remarks that, because the cells of the tubuli contorti remain uncoloured during the excretion of carmine, we are not entitled to conclude that they do not take a part in the process. From the investigations of Gerlach, we know that carmine does not adhere to living cells; it is therefore not impossible that the carmine, like the indigo-carmine, may have passed through the cells of the tubuli contorti, without, however, being fixed by them. But the opposite peculiarity must be shown in the case of indigo-carmine, *viz.*, that it can be precipitated in the protoplasm of living cells.

DROSDOFF AND BOTSCHETSCHKAROFF ON THE CONTRACTION OF THE SPLEEN AND ITS RELATION TO THE LIVER DURING STIMULATION OF THE SPLENIC NERVES.—Drs. Drosdoff and Botschetschkaroff (*Centralblatt für die Medicinischen Wissenschaften*, no. 5, 1876), were led, by the observation of Botkin that the liver increased in size where the spleen contracted under the influence of the induced current, to investigate the relation of the spleen to the liver in animals. The spleen and liver were exposed in a narcotised dog. The quantity of blood in the portal system was estimated by introducing a manometer into the splenic vein; the results were the following. 1. On section of the nerves of the splenic plexus, the spleen increased in all directions, and on stimulating the peripheral ends of the nerves it diminished in size. 2. When the contraction of the spleen produced by stimulating the peripheral end of the nerves commenced, the liver began to increase in size. The hepatic lobules

became sharply defined, their colour deepened, and their tissue became firmer. When the spleen increased the liver again became smaller, its borders sharper, the outlines of its lobules disappeared, its tissue softened. 3. After every contraction of the spleen the number of white blood-corpuscles in the liver increased. This observation agrees with the results of Tarchanoff and Swan (LONDON MEDICAL RECORD, August, 1875). 4. Stimulation of the splenic nerves increased the pressure in the splenic vein. 5. Ligation of all the splenic vessels did not completely extinguish the power of the spleen to increase and to contract, but only diminished this property.

ARNDT ON THE GANGLIONIC CELLS OF THE SPINAL GANGLIA.—R. Arndt (*Archiv für Microscop. Anat.* vol. xi., *Centralblatt für die Medicinischen Wissenschaften*, no. 5, 1876) finds that the typical form of the cells of the spinal ganglia is a more or less irregular flat disc. They are at least bipolar. The author believes that multipolar cells also exist, which, in addition to two strong and well marked processes, send out a number of finer ones, which are, however, easily torn off or overlooked. Arndt was unable to convince himself of the existence of unipolar ganglionic cells. The apolar bodies which do occur in the spinal ganglia, the author regards as the result of an anomalous development. The two chief processes of the ganglionic cells generally arise very near each other. In many cases each process arises from the ganglionic cell by itself, and is enclosed in a special sheath, which is a continuation of the capsule. In other cases, the two processes approach each other, and are enclosed in the same sheath. They are medullated almost at their origin, but the author has observed processes originally non-medullated.

MALASSEZ ON SOME VARIATIONS PRESENTED BY THE TOTAL AMOUNT OF THE BLOOD.—Malassez (*Archiv de Physiologie*, 1875, p. 261, and *Centralblatt für die Medicinischen Wissenschaften*, no. 11, 1876) has continued his researches on this subject in Ranvier's laboratory. By the term 'blood-corpuscle capacity' (*capacité globulaire*), the author expresses the quotient obtained by dividing the absolute number of blood-corpuscles by the weight of the animal expressed in grammes. A rabbit weighing 2,450 grammes has 919,450 millions of blood-corpuscles, and, according to the above, a blood-corpuscle capacity of 373 millions.

By the term 'richness in corpuscles' (*richesse globulaire*), the author means the number of blood-corpuscles contained in a single cubic millimètre of blood. Following these two data throughout the animal series, it is shown that the *capacité globulaire* is greatest in the mammalia (rat 630 millions, rabbit 373 millions). It is generally less in birds than in mammals. It is very considerably diminished in the osseous fishes, more so in the cartilaginous species and the amphibians (torpedo two to six millions, frog seventeen millions, proteus two millions, axolotl one to four millions). The *richesse globulaire* also diminishes in the animal kingdom in the same direction as the *capacité globulaire*, but the two curves do not run parallel, in as far as the latter sinks more rapidly than the former. By the smaller decrease of the *capacité globulaire* the greater diminution of the *richesse globulaire* is counterbalanced, and in a certain sense compensated for.

While in the lower animals both the *capacité* and *richesse globulaire* are less, the dimensions of the blood-corpuscles are much greater. One might assume that the smaller number was thereby compensated. According to the author, this is not so. Under all circumstances the lower animals are at a disadvantage, and have a smaller quantity of blood than animals higher in the scale.

The author has made extended observations on the influence of age on the number of blood-corpuscles in the rabbit, rat, guinea-pig, dog, cat, chick, and frog larvæ. In mammalia, that both *capacité* and *richesse globulaire* rise after birth and reach their highest point in the third or fourth week of life; they then begin to fall, and sink below the point at which they started. In adult animals both seem to rise again considerably. In the chick, the *capacité globulaire* scarcely varies during the whole time of incubation; after birth it sinks pronouncedly; it rises again in the adult, without, however, again reaching the height which it attained during the embryonal condition.

Investigations on animals under different hygienic conditions, e.g. starvation, feeding, etc., gave as the general result that the *capacité globulaire* always diminished when the hygienic conditions were not so good, or when the general condition of the animal was in any way deteriorated. A case of transfusion, in which M. ascertained the *capacité* and *richesse globulaire* both of the person who gave the blood, and the one into whom it was transfused, is employed by the author to calculate the quantity of blood in both persons. For the one who received the blood, the quantity of blood was one-seventieth of the body weight; for the other one-ninth, which numbers agree exactly with those of Lehmann, Weber, Welcher, and Bischoff.

KLUG ON THE BLOOD-CURRENT IN THE CORONARY ARTERY OF THE HEART.—F. Klug (*Centralblatt für die Medicinischen Wissenschaften*, no. 8, 1876) cites an experiment to prove the truth of a remark of Brücke, 'That the capillaries during the contraction of the cardiac muscles are so compressed that they are caused to disappear.'

The hearts of two frogs were exposed; the one was ligatured during the systole, the other during the diastole. The hearts were then excised, and placed in dilute sulphuric acid, in order to cause coagulation of the blood. The muscles of the heart stopped during diastole was rich in blood, whilst the one ligatured during its systole showed only traces of blood in its outer layers. The same experiment was repeated on a rabbit with the same results.

PATHOLOGY.

SENFTLEBEN ON THE CAUSE OF KERATITIS AFTER SECTION OF THE TRIGEMINUS.—Senftleben (*Virchow's Archiv*, vol. lxx.) remarks that section of the trigeminus in its intracranial course in rabbits, whether a small or a large part of the nerve be left intact, is always followed in from ten to twelve hours by a distinct opacity of the cornea, as soon as the eye is left without a protective covering. This opacity never reaches the margin of the cornea; after several hours a cloudy (secondary) opacity gradually proceeds inwards from this point. The cause of the primary opacity is not the evaporation favoured by cessation of the closure of the eyelids, for when the eyes were covered at once by coarse wire-gauze no change occurred. The cause is not to be sought for in certain trophic nerve-fibres contained in the trigeminus, for the diseased eye reacts to the same stimuli as the sound one; nor is there any difference either regarding the origin or course of the affection from that in the sound eye, in which exactly the same affection, running the same course, can be produced by traumatic stimuli. The affection is therefore to be ascribed to traumatic influences, to which the anæsthetic eye is continually subjected, and therefore does not appear when the eye is carefully protected from the first.

The microscopic investigation of the changes produced in the cornea by section of the trigeminus, as well as by direct mechanical stimulation, showed that the primary opacity is not caused by an inflammation (*i.e.* suppuration), but by a circumscribed necrosis, marked off sharply in all directions peripherally from the normal surroundings, but not so sharply defined towards the substance of the cornea itself. This necrosis is marked off by a wavy line, which is indicated specially by an indistinctness, and latterly (after twenty-four hours) by a disappearance of the cornea corpuscles (and of the epithelial cells). This necrosis produces a suppurative inflammation (secondarily), which results in a diffuse secondary opacity of the margins produced by the wandering white blood-corpuscles.

The cells do not penetrate into the necrotic parts, but collect at the margin and completely dissolve it, so that a loss of substance takes place, which, however, is soon replaced, so as further traumatic influences are prevented. That the primary affection is a necrosis was shown by its relation to bile-pigment, which tinges the necrotic but not the living parts. The simultaneous extirpation of the superior cervical ganglion is without influence on the occurrence and course of the affection of the cornea following section of the trigeminus.

WM. STIRLING, D.Sc., M.D.

SNELL ON THE MORBID ANATOMY OF EPILEPSY. In the last number of the *Zeitschrift für Psychiatrie* for 1875, a report is given of a paper by Dr. Snell in which he relates the results of the *post mortem* examinations of 100 insane epileptics.

The first point noticed was the fact that epileptics are more short-lived than other lunatics; the average age of the hundred at death was thirty-three years, a very low one considering that all the patients were over fourteen, and most over twenty, when they were admitted to the asylum where the observations were made. Only eight exceeded the age of fifty, and one was over seventy, but he had not become epileptic until past sixty.

As to the cause of death, the large number of 47 had died either in a fit or in the comatose state which often follows. In these cases the seizures were either very violent or frequently repeated. Such deaths are usually ascribed to brain-paralysis, but Dr. Snell thinks they are caused by interruption of the respiratory process; this disturbance of respiration is evident during the fit, and, after death, the brain does not usually present any appearance which may be directly referred to a sudden change of blood pressure; on the other hand, in the lungs, especially after the slower form of death, œdema is frequent, and hyperæmia and even hypostatic hepatisation are not uncommon. In the 47 cases, œdema occurred 15 times, hypostatic hepatisation 6 times, and hyperæmia frequently in the remaining cases. In one case the lungs were unaltered, but this also occurs occasionally in asphyxia from other causes. In only two of the cases was there extravasation of blood between the membranes.

The next most frequent cause of death was tuberculosis of the lungs; it occurred in 31 cases, generally in the form of caseous deposits and softening. Tuberculosis was often present in other organs, but only once in the meninges of the brain. In one case there was abscess, and in another gangrene, of the lung. In a few instances the liver and kidneys were diseased, and in one case there was a great displacement of the transverse colon.

The appearances in the brain were very various. There were two cases of injury to the skull and brain. The first case was that of a man who was kicked on the head thirty-five years before death; an old fracture was found on the right frontal eminence; the membranes were adherent beneath it; and a cyst, of the size of a hazel-nut, filled with turbid fluid was found in the corresponding convolution. Numerous calcareous plates were found on the posterior surface of the cauda equina, and there was œdema of the lungs. The other case occurred in a boy who received a punctured wound near the outer and upper border of the os frontis at four years of age; he died at seventeen, and a splinter of bone was found projecting inwards at the seat of injury; the membranes were adherent all around, and there was a corresponding depression a quarter of an inch deep in the second frontal convolution. The lungs were œdematous.

Two cases of cysticercus of the brain are given. A man died at sixty-one, having been epileptic seventeen years, with large delusions. In the cortical substance of both hemispheres were numerous calcified cysticerci of various sizes, up to that of a pea; there were also several in the grey matter of the right corpus striatum. There was œdema of the lungs. A woman died at thirty-four, having been epileptic six years, and suffered from delusions of persecution and hallucinations of several senses. There were a cysticercus half an inch in diameter in the right corpus striatum, and five other smaller ones in the cortical substance at the base of the middle and anterior cerebral lobes. There was œdema of the lungs.

Two cases of medullary cancer of the brain are related. The first was that of a man who died at thirty-eight. He had been epileptic nine years, and had had hallucinations of smell and hearing, with periodical attacks of melancholy. After death a mass of medullary cancer was found on the left side of the base of the brain, compressing the pons Varolii and optic nerve; it invaded all three lobes of the

hemisphere, and was connected with a cyst of the size of a hazel-nut in the floor of the anterior horn of the lateral ventricle. The greatest diameter of the new growth was one inch and a half. The lungs were œdematous. The second instance was that of a man who died at thirty-three, epileptic two years, had had large delusions and hallucinations and attempted suicide; there was a cancer of the size of a hen's egg in the right posterior cerebral lobe, projecting into the posterior horn of the lateral ventricle and into the middle lobe; the hippocampus was completely absorbed by the tumour. This patient died after a succession of twenty-three fits in three hours. The lungs were œdematous. In neither of these cases was any motor paralysis observed.

Three cases of morbid changes in the hippocampus major, to which Meynert has drawn attention, are given. 1. H. H. had fever at seven, was thenceforward imbecile, became epileptic at sixteen, and developed large delusions. He died at twenty-four; and the left hippocampus was found sclerosed. Tricuspid stenosis and insufficiency were also present. 2. W. S. was demented and epileptic ever since an attack of meningitis (?) in childhood. He was maniacal after the fits. After his death, at nineteen, the left cornu ammonis was found to be shrivelled into a hard thin cord, consisting almost entirely of connective tissue. There was œdema of the lungs. 3. W. W., rather imbecile from birth, became epileptic at seven. He was inclined to violence and had a distinct affection of speech; he stammered and had great difficulty in forming a sentence. He died at twenty-six: both hippocampi were seen to be reduced to hard bands, their ependyma was rough and leathery, and the ependyma of the fourth ventricle was folded and thickened. The lungs were œdematous.

In one case there was a calcareous mass in the superior vermiciform process of the cerebellum; the patient had been long epileptic, was demented and often excited. One instance was observed of caries of the petrous bone, with softening of the neighbouring parts of the brain; the patient had been thirteen years subject to epilepsy with periodical excitement.

In four cases out of the one hundred the pia mater was found firmly adherent to the convolutions as it frequently is in general paralysis. All four patients were deeply demented, and three of them had been epileptic since their earliest childhood.

CHAS. S. W. COBBOLD, M.D.

LETZERICH ON DIPHTHERITIC ENCEPHALITIS.—In Virchow's *Archiv* (1875, p. 419) is an article on diphtheritic encephalitis, by Dr. Ludwig Letzerich of Braunsfels. It is based upon a case which had lately occurred in his own family. A strong and well-formed male infant was noticed, ten days after birth, to have diarrhoea, which was attributed to some slight digestive disturbance. It then began to refuse its food, and on examination of the mouth and throat the hard and soft palate were found to be in a state of extreme injection, while the tonsils and arch of the palate had diphtheritic membrane upon them. It should be said that since the birth of the child five persons affected with diphtheria, including two children, had come from the town or country to the house, and all had been treated by the local application of salicylic acid. The child had no fever or suppression of urine, which would convey the idea of a general diphtheritic state; therefore the treatment was confined to purely local measures, salicylic acid being dusted over the part.

Under this treatment the amount of the exudation diminished, though it returned to some extent. Still, by the eighteenth day the mucous membrane was quite free. Notwithstanding a free diet and the administration of stimulants, the child gradually sank, fourteen days after the cessation of the local disease. It had been remarked that it always remained very quiet, and without taking notice of external things, and was very drowsy; and these symptoms, together with its habit of sleeping with its eyelids open, and a peculiar cry, led to the idea that there might be some congenital deficiency of the brain, which had only gradually forced itself into notice, and that a local disease in the throat independent of it had brought about the fatal termination.

The head was opened five hours after death. Both parietal bones were hyperæmic at their hinder parts. The vessels of the dura mater, contrary to the bloodless state of the rest of the body, were gorged with a dingy fluid blood. The surface of the brain was very pale, but the substance showed blood-puncta on the surfaces of all sections. Extreme engorgement existed both at the base of the skull and at the base of the brain. The remarkably pale colour of the grey substance, especially of the fore and middle part of the right hemisphere, first of all attracted attention. On section, the grey substance seemed at first sight to be wanting, but on attentive examination one could observe a much distorted and faded boundary between the grey and the white matter. The right side of the cerebrum was œdematous and soft—conditions which seemed to have conduced to shrinking of the right lateral ventricle, and to a consequent want of symmetry in the two halves of the brain. The cerebellum was small. The proper contrast between the colours of its various parts was wanting, and in its leaflets were small round grain-like formations which projected visibly from the cut surface. The other viscera were not examined. The brain was examined in the fresh state and after hardening. The middle part of the right hemisphere was unusually soft, and its neuroglia was finely granular, many nuclei being embedded in it. [This description appears to indicate the existence of an inflammatory nucleated protoplasm undergoing granular changes.—*Rep.*] Besides the nuclei, bacteria in active movement, of much variety of form, and in unusual numbers, were found, groups of which, clustered together, occupied the interior of the ganglion-cells, the protoplasm of which was, with this exception, clear, though sometimes changed into glassy non-nuclear masses. It was found impossible to isolate the ganglion-cells. The examination of the front part of the right hemisphere gave a similar result to that of the middle part, except that the neuroglia-cells were less numerous, and the nerve-cells completely destroyed, their pericellular spaces empty, and their walls undergoing exuberant growth of plasma-cells.

The author thinks that, as in other organs of the body, the bacteria came by way of the lymph and blood-vessels. He has seen them developing outside the vessels after having penetrated the membranous wall. In such vessels the red blood-cells, while retaining their form, had lost their colour. The altered blood-cells were so dense in places as to obscure the vessels, and capillary hæmorrhages wanting in red colour are described.

The grey matter of the cerebellum was in a similar state, except that the nuclear proliferation was less marked, and the pericellular spaces less often filled by inflammatory products.

In the white substance, however, there was an extreme increase in the neuroglia-cells, amounting to millet-seed-sized nests, visible to the naked eye, and which were not unlike the section through a glioma of the brain. The ganglion-cells in the neighbourhood of each nest of cells were not so much altered as in the grey substance proper, or in the fore and median parts of the right cerebral hemisphere, and they could therefore be isolated with their contained bacteria. Their protoplasmic prolongations had not the hyaline appearance of normal cells, but were in a state of granular degeneration, and were densely beset with bacteria. The white substance of the cerebellum seemed normal, but here and there bacteria and granulation-cells were found between the fibres. In the white substance of the right hemisphere they were more numerous and in dense clusters, and the fibres, in consequence of a granular exudation, showed some indistinctness of structure. In the grey ganglia of the right lobe of the cerebrum, and in the cerebellum, micrococci were present, though only in inconsiderable number.

At first sight it is, indeed, remarkable that the grey substance of the brain should by preference allow these diphtheritic organisms to flourish in it and so cause its molecular destruction, while the white matter is much less affected. But a sufficient explanation of this is to be found in the difference in the distribution and in the course of the blood-vessels in the two tissues (grey and white). In the white matter the vessels have a much straighter course than in the grey, in which numerous anastomoses and loopings are found; and it is in these and in the many abrupt angles of the vessels—notably of the small anastomosing capillary venules—that diphtheritic organisms easily collect and thence extend by active growth in the connective of the organ. Thus it comes that the grey substance, in which such favourable conditions exist, is by preference more extensively attacked and destroyed.

The very distinct diminution of the cerebellum and the increase of the right hemisphere of the cerebrum are worthy of notice. Both changes had their origin in one and the same cause; since the greater part of the grey and the whole of the red-coloured substance of the small brain were destroyed by the fungus, and therefore wasted, the organ was of necessity smaller; the white matter was but sparingly attacked, and had almost a normal appearance. In the right cerebral lobe a very considerable amount of exudation-matter was present, both in the grey substance and between the white fibres. Therefore the lateral ventricle, as that part upon which an enlargement due to inflammatory exudation would most encroach, was smaller than its fellow.

From the pathological changes in the grey substance of the right cerebral lobe followed the above-mentioned symptoms, which were similar to those which are found after the removal of the hemisphere for physiological purposes.

The starting-point of the disease was, no doubt, the circulatory disturbance, which was present here as in all parts affected by diphtheritic organisms. Thus originated the vascular engorgements (by fungus-embola), the œdema of the tissue, and even the formation of watery exudations on the free serous and other membranes. From the appearances found, death may be said to have followed upon a gradually developing diphtheritic paralysis of the brain.

EICHHORST ON HÆMORRHAGE INTO THE SUBSTANCE OF THE CORD.—Eichhorst (*Charité Annalen* for 1874, Berlin, 1876), publishes a case of primary hæmorrhage into the cord, which, he thinks, sets at rest this *quæstio vexata* in pathology. The patient was taken ill on July 28, and died on August 1. On microscopic examination he found the vessels of the cord filled with blood-corpuscles and sacculated; the structure of the walls seemed perfectly normal; some were ruptured, and extravasations into the lymphatic sheaths or into the substance of the cord were seen. There was no change in the nerve-cells or nerve-fibres, no division of nuclei nor fatty degeneration. In some of the older extravasations a few granular corpuscles were seen. He can give no explanation of the etiology of the case; it was not traumatic, nor could it be called metastatic as the patient has always menstruated normally, and that function had been fulfilled at its accustomed period a few days before her seizure.

MEDICINE.

FRÄNTZEL ON THE OPERATIVE TREATMENT OF METEORISM.—Fräntzel (*Charité Annalen* for 1874, Berlin, 1876), after a pretty large experience in the treatment of puncture, concludes that it should only be undertaken in cases of peritonitis when death is imminent. He draws attention to the differential diagnosis of meteorism and gas in the cavity of the peritoneum, pointing out that the disappearance of the liver-dulness, and the absence of the metallic clang audible when the abdomen is auscultated and percussed simultaneously afford trustworthy indications of the latter condition when unconsciousness or heightened subjective impressions on the part of the patient, make reliance upon pain or tenderness impossible or untrustworthy.

EICHHORST ON CONSTRAINED MOVEMENTS IN BRAIN-DISEASES.—Eichhorst (*Charité Annalen* for 1874), following the physiological observations of Vulpian and Prévost, directs attention to the involuntary movements sometimes following apoplexies and other lesions of the brain. The patient lies on the right or the left side, and the head and eyes are turned to the same or the opposite side; if the position be changed by the attendants, the body soon recovers its previous posture. He thinks this affords a means of localising the lesion, for if both body and head are drawn to the same side, the lesion will be found on the opposite side; if only the head be drawn, the lesion exists on the same side; in some cases of deep coma this may be a valuable indication of the site of the lesion.

SOKOLOWSKI ON A CASE OF ACUTE IDIOPATHIC ENDOCARDITIS, WITH SUBSEQUENT EMBOLISM

OF THE LEFT MIDDLE CEREBRAL ARTERY, CEREBRAL SOFTENING, AND DEATH. — No. 13 of the *Deutsche Medicinische Wochenschrift* (December 18, 1875), reports the following case, from the pen of Dr. Alfred Sokolowski, late of the General Hospital of Warsaw, into which the patient, a servant-girl, aged twenty-three, was admitted on October 1, 1873. She stated that for four days, without any known cause, she had suffered from alternate heats and chills. Once or twice she had slight shivers and headache, as well as a general feeling of weariness, and loss of appetite. The catamenia had been regular ever since her fifteenth year. She had been confined two years before, without any untoward event. In fact, she had only suffered from indigestion. On admission, her pulse was 100, and temperature 102.6° Fahr. Physical exploration of the abdomen and lungs disclosed nothing abnormal. The limits of cardiac dulness were normal. On auscultation a soft systolic limit, resembling a friction-sound, was heard at the apex. The second sound was quite normal, but was heard badly at the base of the sternum and immediately followed by the murmur. The latter was not well heard at the base of the heart. Indeed, at the level of the fourth ribs, both sounds could be heard free from murmur. She passed about 1,500 cubic centimètres (about 53 ounces) of urine, of specific gravity 1,020, in the twenty-four hours. It was somewhat acid. In the evening her temperature was 104° Fahr. Pulse 100 as before. During the next two days her condition was as follows. Her pulse varied between 84 and 98. The morning temperature was 101.2° Fahr.; the evening 103° Fahr. On the third evening, percussion showed slight enlargement of the right ventricle, and the second tone of the pulmonary artery was accentuated. There was no enlargement of the spleen. Acute idiopathic endocarditis was diagnosed. From October 4 to 12 there was but slight alteration in the symptoms. The medication consisted in regulation of the diet and bowels, and the use of bark and digitalis. On the morning of October 13 it was noticed that she had become paralysed on the right side, and at the same time had quite lost her speech, so that she was only able to give a sort of cry of distress (*Klage-laut*) from time to time. She heard well with the left ear, and answered questions by signs. The pupils were not altered, but the left corner of the mouth was drawn. There was complete anæsthesia of the paralysed parts. Urine and fæces were passed unconsciously. The spleen was enlarged, and very tender on palpation. The temperature was 102.2° Fahr. Pulse 90. The heart-sounds were unchanged. The second tone in the pulmonary artery was strongly accented. In the evening her temperature was 104.8° Fahr. Pulse 100. Sensibility began to return in the right leg, below the knee, and she could move the right foot slightly. Otherwise her condition was as in the morning. The diagnosis now made was embolism of the middle cerebral artery on the left side, and embolism of the splenic artery—based on the sudden occurrence of right hemiplegia, the sudden enlargement of the spleen, the disturbances in her hearing and in the faculty of speech; the previously diagnosed endocarditis, and the youth of the patient, rendering cerebral hæmorrhage less probable. The loss of speech was quite peculiar. She seemed unable to articulate anything, except a sort of cry from time to time. Yet she made her wishes known, and answered questions by signs. There was thus a loss of articulate speech

(alalia) whilst thoughts continued to be formed in the brain, which she could not express in words. There was the form of alalia which Professor Jaccoud (*Leçons de Clinique médicale faites à l'Hôpital Lariboisière*, Paris, 1873) rightly calls logoplegia. October 14. Power of movement in the extremities, and speech, gradually returned. Morning temperature 102.2° Fahr., pulse 90. Evening temperature 103.8° Fahr., pulse 100. October 15. All paralysis and alalia had vanished. She was extremely weak. She answered questions rather glibly, but with full consciousness. In the course of the next twelve days she became gradually weaker. The evening temperature varied between 102.2° and 104.8° Fahr., the morning between 100.8° and 104° Fahr., the pulse between 88 and 100. Pneumonic symptoms set in. She lost her appetite, and suffered alternately from constipation and diarrhoea. The splenic enlargement and tenderness remained. The urine was now only from 800 to 1,000 cubic centimètres (= 28 to 35 ounces) and contained albumen. It contained urates, and hyaline casts. From October 29 to November 10 she was still worse. She no longer answered at once to questions, but repeated the same word over and over again. She even lost memory of her own name. The fever increased; the evening temperature rose to 105.2° Fahr.; the pulse was 120, and thready. There was more bronchitis, and some exudation into both pleural cavities. The quantity of urine decreased, the albumen increased. There were now signs of softening of the brain. Could this be localised? It seemed possible. Whereas the older French writers (Boillaud, Broca, Trousseau, and others) placed this spot in the midst of the third frontal convolution (*stella Brocæ*) the latest French observers, especially Jaccoud (*loc. cit.*) announce that the seat of the lesion is not very definitely fixed, but that it is commonest in the left corpus striatum and the island of Reil, and in the frontal convolutions, especially the third. Dr. Sokolowski's own experience led him to believe that this cerebral softening was in one or more of these regions. On November 12 the patient responded easily to questions, with full consciousness. There was, however, no improvement in any of the symptoms. Her tongue was dry, and she had diarrhoea. Both lungs now showed hypostatic pneumonia. On November 20 she died, quite conscious to the last.

The necropsy was made by Dr. Przewoski. The chief points were as follows. The arteries at the base of the brain were healthy, except the middle cerebral artery on the left side, in which a semi-transparent embolon of cartilaginous consistence was found. The right side of the brain was healthy, though rather pale. So was the left, except that the cortical substance of the island of Reil, the grey matter of the corpus striatum and of its lenticular nucleus were smaller, harder, and yellower than normal, and had a reticulated appearance—in other words, softening, with subsequent cicatrisation (*Vernarbung*) of the softened parts. There was fluid in the peritoneal and in both pleural cavities, and a little in the pericardium. The heart was greatly enlarged, especially on the right side. The walls of the left ventricle were not thickened. There were numerous yellow spots under the endocardium. The edges of the mitral valves were much thickened, and covered with numerous coagula of blood, some as large as a walnut; these clots were all attached to ulcerated patches in the thickened upper borders of the valves. The

right ventricle was much enlarged, otherwise normal, as were the aorta and pulmonary artery. The spleen was thrice its normal size, dark red, and had numerous sharply bordered 'blocks.' The liver was normal. The kidneys were about one and a half time: their normal size; their cortical substance was thickened, with small infarctions, forming the base of small cavities. The left kidney was largest, and slightly granular. The mucous membrane of both large and small intestine was thickly coated with mucus. The stomach, bladder, and genitals were normal.

Dr. Sokolowski remarks that primary acute endocarditis is very rare. Niemeyer would not admit it. Bamberger, Friedreich, Von Dusch, and Oppolzer, whilst admitting it, consider it as extremely rare. He also notes Professor Brodowski's observation, that the suddenness of the brain-symptoms, in connection with the loss of speech, is of great importance. For in case of tumours, growing slowly, the whole region may be involved without loss of speech. The vanishing of both the paralysis and loss of speech in forty-eight hours is of extreme interest. No doubt the collateral circulation was then established. Quite fourteen days afterwards, the softening seems to have attacked the cortical substance, and brought about the gradually developed condition of depression, mechanical repetition of words, etc., and loss of memory. From November 12 the depression decreased, consciousness returned, and was again perfect three days before death—symptoms which may be due to cicatrisation of the affected parts, and the vicarious action of the other cerebral hemisphere. [The reporter has given this case at some length, and as far as possible in the words of the author. It is of great interest, as confirming the views which Hughlings Jackson, Ogle, Broadbent, and other English observers have long taken, especially the former. The translator ventures, however, to think that the general course of the symptoms was probably due to enteric fever; in other words, typhoid or pythogenic fever, which never became localised in the abdomen, but spent its force on the heart, and perhaps on the kidneys. It seems also not improbable that the mechanical or parrot-like repetition of words at one period was due to poisoned blood, since the partial suppression of urine and the albuminuria are not unlikely to have given rise to uræmia at that date. Monotony is a marked character of toxæmic (especially uræmic) delirium.—*Rep.*]

LOOMIS ON PERITONITIS, AND ITS 'HEROIC' TREATMENT BY OPIATES.—The Clinical Lecture from which we quote, is no. 9 of 'A Series of American Clinical Lectures,' edited by Dr. E. C. Seguin, and published by G. P. Putnam's Sons, New York. Dr. Alfred L. Loomis is Physician to Bellevue Hospital, New York, and Professor of Pathology and Practical Medicine in the New York University. His remarks are founded on three or four recent cases. The first, a cabinet-maker, aged eighteen years, had enjoyed good health until the last three years. During this time he had had eight attacks before the present one, of intense abdominal pain, nausea, vomiting, and other symptoms of peritonitis. The attacks were preceded by constipation, and usually occurred in cold weather. The present attack followed three weeks after working all day in wet clothes. The pains began just below the navel. His symptoms on admission were those of collapse;

pulse, 120; respirations 40, thoracic; temperature, 101° Fahr.; thighs flexed on abdomen; mind clear. He was given four ounces of brandy per rectum, and morphia hypodermically. Convalescence was fully established seven days after. During that time twenty-one grains of morphia were administered hypodermically. Dr. Loomis remarks on his case that 'the presence of fecal vomiting proves, almost to a certainty, intestinal obstruction to have been the exciting cause of his disease.' Amongst the causes of acute peritonitis he enumerates the following.

1. In intestinal obstructions and perforations; including typhlitis, and perityphlitis, with ulceration; rupture of hepatic and other abscesses; ulceration and rupture of the stomach, of the gall or urinary bladder, hydatid cysts and aneurisms—in all these cases, the inflammation spreads rapidly over the entire peritoneum.

2. The extension to the peritoneum of inflammation from organs covered by peritoneum is found in cases of general peritonitis from the uterus and its appendages, the liver, spleen, venous thrombi, typhlitis and perityphlitis without ulceration. In all such cases the peritonitis remains for some time circumscribed. Peritonitis from contusions and penetrating wounds must be studied from a surgical standpoint.

3rd. In very many instances acute general peritonitis is the immediate result of an infection. Puerperal peritonitis, and the peritonitis which develops in the course of an infectious disease, as pyæmia, septicæmia, etc., may be classed under this head. The latter form should be regarded as a distinct type, and need not be discussed here.

The next case recorded occurred in a previously healthy man, aged sixty-one. It terminated fatally in twelve hours. There was a good deal of lymph effused, and the cause appeared to be diverticula in the descending colon, filled with fecal matter: these seemed to be the result of hernia of the mucous membrane through the muscular coat of the intestine, the sac in each being formed of peritoneum and mucous membrane. No openings were found in any of them, but their peritoneal surfaces were the seat of the most intense inflammation: Undoubtedly peritonitis existed when this patient's pulse was eighty.

Another case is given in some detail, of obstruction of the bowels, and peritonitis from firm fibrinous bands about the small intestine, with calcareous degeneration of the mesenteric glands. The patient was aged twenty-one, and the gland mischief and fibrinous bands probably existed from childhood. Another case is given of ulcerating sarcoma of the stomach, in a merchant aged forty-six. Another patient, aged thirty-four, had a pelvic abscess, with perforation of the vermiform appendix. These consecutive histories show 1st, that acute peritonitis is rarely, if ever, of spontaneous origin; and 2ndly, how difficult it often is to determine the cause. Dr. Loomis insists strongly upon 'the boiled spinach' character of the vomiting of peritonitis, fecal vomiting indicating obstruction. The symptoms and differential diagnosis are next given at some length, and with great clearness. English readers will, however, take more interest in the treatment advocated by Professor Loomis. For at least half a century the use of opium has been the practice of English medical men in the treatment of acute peritonitis. In America, however, Dr. Alonzo Clark has advocated a more heroic use of opiates. The details of this plan are as follows. 'As soon as you have decided that your

patient has acute peritonitis, administer at once from two to five grains of solid opium, or from one half to a grain of morphia. The exact quantity in each case is to be determined by the condition of your patient. As a rule, to a strong vigorous male you may give four grains for the first dose; to a feeble female it is not well to commence with more than two grains.' Dr. Loomis goes on to say:—'I have administered to patients with peritonitis four grains of opium every two hours for twenty-four hours, and then have obtained only a moderate effect of the drug. The point which you wish to reach in this disease is moderate narcotism, in which state you must strive to keep your patient, not only until all pain and tenderness have subsided, but until the pulse has reached a normal standard, and the tympanitis has entirely subsided.'

[Although 'moderate' narcotism is recommended, the symptoms described are those of a more extreme and dangerous degree. It is fair to Dr. Loomis to state that he says 'Avoid extremes—if you find it difficult to rouse your patient, stop the administration of opium.' Yet the reporter thinks the administration of forty-eight grains of opium in twenty-four hours, except to opium-eaters, is a dangerous practice. Some of the fatal cases recorded in the lecture seem to have been deeply narcotised. Surely if pain be relieved, and the bowels kept perfectly quiet by moderate doses of opium, no good purpose can be served by these heroic measures.—*Rep.*]

SURGERY.

LEONPACHER ON PNEUMOPERICARDIUM TRAUMATICUM.—An instance of this rare lesion has recently been reported by Dr. Leonpacher of Traunsteid (*Aerztliches Intelligenz-Blatt*, no. 44, 1875). The patient was a robust man-servant, aged thirty-six years, who, in an accidental fall from a hay-loft, struck his back violently against the ground. He at once suffered from severe pain and from dyspnoea, and was unable to raise himself. When first seen by Dr. Leonpacher, a few hours after the accident, he was lying in bed on his left side, and complained of much pain in the left half of the chest, and of shortness of breath. The respirations were very rapid, the pulse 92. Over the middle line and on the right side of the vertebral column, and between the ninth dorsal vertebra and the first lumbar vertebra, there was a subcutaneous collection of blood, which was very tender, and from which, on pressure, pains radiated towards the umbilical region. There could be heard, even at a short distance from the patient's bed, two loud and rapidly successive sounds,

one of which was isochronous with the impulse of the heart's apex, and of shorter duration than the other. Both were gurgling sounds, and resembled in their character the sound as of fluid being poured out of a bottle. These sounds intermitted, so that at times, for a short period only, the normal cardiac sounds could be heard. The impulse of the heart's apex was visible at a point one centimètre external to, and two centimètres below, the left nipple. On percussion, a tympanic sound was heard over the whole of a space bounded above by the third costal cartilage, below by the fifth rib, internally by the left margin of the sternum, and externally by the left nipple. Inferiorly the tympanic area was continuous with that of the clear sound over the stomach; externally there was a band about an inch in breadth, along which the sound was dull, between it and the resonant sound over the left lung. In the left axillary line there was absolute dullness below the level of the heart's apex. On auscultation the normal sounds of the heart could be clearly heard, and were made out to be distinct from the gurgling sounds at the apex. On the second day after that of the accident the patient could lie on his right side; there was no longer any severe pain in the left side of the chest, the gurgling sounds had ceased, and the impulse of the heart's apex could just be felt in the parasternal line above the fifth rib. Externally to this line there was a clear lung-sound. Percussion of the back of the patient gave a dull sound between the spine and a line drawn downwards from the inferior angle of the left scapula. Over this area of dullness no respiratory murmur could be heard, but only occasional rhonchus. On the fifth day after the accident, the swelling in the back was much smaller, there was pain only on deep inspiration, and all that the patient complained of was a slight cough. Pressure over the lower dorsal vertebræ no longer caused pain, the area of dullness at the back of the chest was much reduced, and a low respiratory murmur could be heard over the lower part of the chest on the left side. In the course of a few weeks the patient became quite well. In this case, the sudden occurrence of the lesion in a man who previously had been quite well, its traumatic origin, the presence in the pericardial region of a distinctly tympanic sound, surrounded by other percussive results, as a sonorous lung tone above, a narrow longitudinal band of dullness externally, which corresponded to extravasation of the pericardium, a tympanic stomach-tone below quite distinct from the clear sound above, the peculiar sounds heard during the movements of the heart, which were quite distinct from the normal cardiac sounds—all these striking symptoms were diagnostic of the presence of air in the pericardial sac. There were probably also some effusion of blood into this sac, and another distinct extravasation into the left pleural cavity. The author thinks that, as there was no pain in swallowing, and no pain or signs of irritation on the part of the stomach, the air collected in the pericardium came from the lungs, and that it probably passed from the left lung into the sac, through a rupture involving the seat of an old adhesion between the two structures.

RAVOTH ON VARICOCELE.—Professor Ravoth is of opinion that morbid irritability and neuralgia of the male genitals are almost always due to some local cause, and especially to varicocele (*Medicinisches Chirurgisches Central-Blatt*, no. 46, 1875). This surgeon states that for some years past he has treated

very successfully varicocele and phlebectasis of the saphena vein by truss-pressure. In almost all the cases of varicocele treated by him, he has found associated with this variety of phlebectasis irritable conditions of the genitals, indicated by frequent pollutions, defective coitus, testicular neuralgia, etc. He has never yet met with an instance in which these conditions did not cease on the disappearance of the varicocele. The author treats varicocele by applying an ordinary hernial truss with a pad, the pressure of which can be regulated by the patient. This truss is so applied that the pad covers the whole of the inguinal canal, and reaches anteriorly as far as the spine of the pubes. This truss is worn usually during the day only, but will prove of much service when worn during the night also, in those cases in which nocturnal pollutions and neuralgia persist notwithstanding the improvement effected by the pressure applied during the day. No other treatment, either for the varicocele or for the other morbid conditions of the genitals, is applied by the author. These morbid and irritable conditions of the genitals may, according to Dr. Ravoth, be successfully treated by truss-pressure even when there is no varicocele. He has never yet seen a case of testicular neuralgia in which there was no varicocele present, but thinks that in rare cases, such as those recorded by Sir A. Cooper and by Curling, in which there was neuralgia of the testicle unassociated with any apparent morbid condition of the spermatic cord or epididymis, truss-pressure, applied as in cases of varicocele, would prove successful in removing or relieving the pain.

VOLKMANN ON THE TREATMENT OF HYDROCELE.—Professor Volkmann reports (*Berliner Klinische Wochenschrift*, no. 3, 1876) seventeen cases of hydrocele treated by free incision of the sac under antiseptic conditions. There is not, according to the author, any better test of the efficacy of antiseptic surgery, than this proceeding of cutting into the sac of an hydrocele. Most surgeons are aware how severe is usually the reaction after this operation when performed in the ordinary way, how profuse is the resulting suppuration, and how slowly the healing processes are subsequently carried on. The almost constant cure of the patient in the course of a very few days, shown by the author's returns, indicates that, through the application of the antiseptic method in free incision of hydrocele, the processes of repair may be modified in a remarkable manner, and that healing may be effected perfectly and with almost inconceivable rapidity. The previously distended layer of the tunica vaginalis unites at once, the author states, with the surface of the testicle by primary adhesion, no local reaction takes place, the patient is able to leave his bed on the fifth or sixth day, and in the course of the second week he is quite well. The following are the details of the operative proceeding which is strongly recommended by Dr. Volkmann. During the operation and the subsequent dressings all the precautions insisted upon by Professor Lister must be rigorously observed. The genitals and inguinal regions are carefully and repeatedly washed with a solution of carbolic acid, and the skin of the pubic and perineal regions is closely shaved. Then, under the carbolic acid spray, the sac of the hydrocele is incised from the region of the external abdominal ring to the most dependent part of the affected side of the scrotum. The exposed and emptied cavity of the

tunica vaginalis is next syringed out with a three per cent. solution of carbolic acid, and the edges of this incised membrane are stitched carefully to the corresponding edges of the incised skin by fifteen, twenty, or even more sutures of very thin silk. All bleeding vessels are ligatured by fine carbolised catgut. The antiseptic dressing is applied closely and firmly so as to maintain the inner surface of the parietal layer of the tunica vaginalis in direct contact with the surface of the corresponding testicle, a small portion of this organ, however, being left exposed between the gaping edges of the incised wound. The prolonged action of the cold carbolic acid spray on the surface of the scrotum during the application of the sutures, and the repeated injection of a cold fluid into the sac of the hydrocele, cause considerable retraction of the dartos, so that this cavity becomes much reduced in size, and its membrane closely surrounds the testicle. In cases where the sac is very large and lax, and also in cases where there is much fibrous induration and sclerosis, it may be necessary to excise a portion of the tunica vaginalis. The most favourable cases are those in which the extent of the sac is so far reduced by the contraction of the scrotum that a small streak of the testicular surface is left distinctly visible between the edges of the wound. The introduction of a drainage-tube is not always necessary. In some cases, however, where the portion of tunica vaginalis forms an elongated funnel with valvular folds on its internal surfaces, a small drainage-tube should be passed as far as the front of the testicle. The blood having been removed from the seat of operation, the scrotum is surrounded by eight or nine strips of antiseptic gauze, and a large piece of gauze in eight layers with a corresponding slit in each layer for the passage of the penis is placed over these. This dressing is closely maintained in its place by a bandage of gauze saturated with carbolic acid. All gaps in this dressing are stopped with portions of salicylised wool, and a large pad of this material is placed in the perinæum between the anus and the scrotum. Absolute hermetical sealing of the wound is a necessary condition of total occlusion of the sac. On the first change of the dressing, the cavity will be found to be quite obstructed, and the wall of the hydrocele-cavity closely adherent to the surface of the testicle.

In all the seventeen cases in which this operation had been performed by Dr. Volkmann, cure was effected speedily and without the occurrence of phlegmon of the scrotum, diffuse suppuration, acute inflammatory cedema, or any kind of swelling of the skin of the scrotum. The importance of this fact, the author states, can be best appreciated by those surgeons who have had experience of cases where hydrocele had been incised without any antiseptic precautions having been taken. In such cases the reaction, both local and general, is almost always very severe. High fever and intense inflammatory swelling of the scrotum usually result, diffuse suppuration attacks the lax cellular tissue of the whole scrotum, the patient is kept to his bed for six or eight weeks, and during the first fortnight is often in a critical condition. In cases where the hydrocele is incised under the antiseptic spray, and the resulting wound dressed in the manner described by Volkmann, there is, according to this surgeon, little if any traumatic fever. The average duration of the treatment in his cases was ten days, and in sixteen out of the seventeen cases total obliteration of the sac had taken place on the third day after the operation.

REINER ON A CASE OF PENETRATING WOUND OF THE ABDOMEN.—Dr. J. Reiner reports (*Medicinisch-Chirurgisches Centralblatt*, no. 42, 1875), a case of a woman, aged twenty-six years, who had been attacked by a bull and severely wounded in the abdomen. The wound commenced on the left side of the linea alba, just above the mons Veneris, and terminated over the right ilium. It was eight inches in length, and five inches and a half in breadth, and involved throughout the whole thickness of the anterior abdominal wall. Through this wound the following structures had protruded; the pregnant uterus (the patient was in the fifth month of pregnancy), two-thirds of the omentum, and a considerable portion of the small intestine. The anterior wall of the uterus presented a large transverse wound, through which the fœtus with the placenta and membranes were discharged. The patient having been carefully removed to her home, and placed under the anæsthetic influence of a mixture of chloroform and ether, the exposed and protruding viscera were returned, and the edges of the wound brought together and retained in contact by pins and twisted sutures. Towards the termination of this operation the patient's condition became very critical, and there was much difficulty in restoring consciousness. Cold compresses were then applied over the lower part of the abdomen, and on the following day morphia was frequently administered in order to relieve pain. On the fifth day the integument, near the left angle of the wound, was marked by some isolated patches of a dark colour, which in the course of the two following days increased in size, and ran together so as to form a large slough, which separated on the thirteenth day, leaving a large orifice in the abdominal wall, through which intestine and omentum could be seen. The patient was feverish during this period, but seems to have presented no symptoms of peritonitis. On the twenty-third day the pulse was 80, the appetite good. The wound was then quite closed along two-thirds of its extent, and the ulcer near its left extremity had contracted very much, the corresponding portion of intestine and omentum being covered over by granulations. During the next fortnight the patient suffered from two large abscesses in the abdominal wall near the wound. Both these were allowed to open spontaneously. On the fiftieth day the ulcer on the left side was of the size of a kreuzer piece, and in its centre was a small orifice, through which passed at times menstrual fluid. Twenty days later the ulcer and orifice were closed, and eleven days after this, at eighty-two days after the injury, the recovery was complete. Menstruation has since taken place regularly, by the natural passage.

HÖNIGSCHMIED ON HERNIA MUSCULORUM.—A case of hernia of the biceps brachii muscle is reported by Dr. Ed. Hönigsmied of Weistrach (*Medicinisch-Chirurgisches Centralblatt*, no. 42, 1875). A muscular and healthy man, whilst lifting a heavy stone with both hands, heard a loud and sudden cracking noise in the left arm. No pain was felt at the time, but on examining the limb the man found that there was a large swelling midway between the elbow and shoulder. Dr. Hönigsmied saw the case soon after the accident, and then observed on the anterior and inner surfaces of the left arm, and in its middle third, a rounded and well defined tumour, of the size of a man's fist, with a broad base, firm and

elastic and immovable. The superjacent skin could be raised from the tumour in folds, and presented no appearance of sagulation. Movements, both passive and active, of the limb could be freely performed; and beyond a feeling of fatigue when the fore-arm was flexed, the function of the limb was not impaired. From these appearances, and the history of the case, the author at once diagnosed it as one of hernia musculorum, and assumed that with the exertion of the arm laceration of the humeral fascia had taken place, and, as a consequence of this laceration, protrusion of the biceps brachii muscle. There was no necessity in this case for establishing a differential diagnosis which, in any instance of this lesion, could only take into consideration some form of tumour. Here the sudden origin and the appearance of the swelling excluded all doubt as to its real character. Tincture of arnica was applied to the swelling, and the man advised to keep his arm at rest. He did not carry out the treatment for many days, but soon worked again as a bricklayer, when he found that he was able to use his left arm very effectually, without experiencing pain, and beyond some slight fatigue, any impairment of function. He noticed that when he was resting in bed the tumour always became much smaller, but that it soon regained its former size when the arm was moved, and whilst he was dressing. According to Dr. Neudörfer, hernia musculorum in most cases is attended with much pain, and causes much impairment of function, and even renders, for a time, the limb immovable and useless. The best treatment, according to this surgeon, is prolonged rest of the limb, and confinement of it in some form of fixed bandage.

W. JOHNSON SMITH.

REEVE ON THE ADMINISTRATION OF CHLOROFORM.—Dr. Reeve, in the *Cincinnati Clinic*, quoted in the *Canada Lancet* for Jan. 1, makes the following remarks. 'There is one stage of the anæsthetic process—a stage especially well marked in robust males—during which the inhalation should be slowly carried on, for it is a stage of special danger. I allude to the struggling stage. You have all seen it doubtless, and must have marked how respiration is interfered with—slow, jerking, or for a time entirely suspended. Over this stage always go slowly. Remember the residual air of respiration—the amount of air always in the lungs, not undergoing tidal movement. It may amount to as much as 250 cubic inches, which, if saturated with chloroform vapour at the temperature of 66° Fahr., would contain the vapour of 30 minims, or nearly twice as much as the average quantity present in the blood of an adult when sufficiently insensible for a surgical operation. That the air is not saturated, and generally not half saturated, is the reason why we do not hear of still more accidents. You will readily understand that this vapour of the residual air is being absorbed even if respiration is entirely suspended, and now if you mark that at the close of this stage, the patient usually draws several deep inspirations, you can see how easy it may be to give an overdose. Keep in mind then the residual air of the lungs during the administration of chloroform, and especially during the stage of struggling.'

W. DOUGLAS HEMMING.

CORRADI ON A CASE OF EXTIRPATION OF THE PAROTID GLAND.—In the *Bulletino delle Scienze Mediche di Bologna* (quoted in *Gazzetta Medica*

Italiana-Lombardia, February 12) is related a case in which extirpation of the parotid gland was performed by Professor Corradi, of Florence.

The patient was a man aged fifty-eight, a Government *employé*, the son of healthy parents. In March 1874, he first felt lancinating pains in the region of the left ear, which gradually spread over the side of the head. He was at first believed to have otitis, and was treated by leeches, ointment of iodide of lead, and a blister to the nape of the neck. When seen at a later date by Dr. Corradi, he was found to have a tumour of the parotid. On his admission into hospital, sensation and temperature were quite normal on the affected side. The left palpebral aperture was a little larger than the right; the left angle of the mouth deviated somewhat towards the middle line, and when he opened his mouth the motor paralysis was still more apparent. In opening his mouth he felt an impediment between the jaw and ear. Deglutition was normal, and no swelling was seen in the mouth or pharynx.

The operation was performed on December 11, 1874. Chloroform was not given, as the patient refused it. The jaw having been carried forward as far as possible, a vertical incision was made from the zygoma to just below the angle of the jaw, passing about a centimètre in front of the ear; a second smaller incision was made transversely from the lower angle of the masseter muscle along the lower border of the jaw as far as the mastoid process. The flaps were dissected up with a knife heated to whiteness by electricity, and the gland was detached from below upwards. When the styloid process was reached, the patient said that he could not close his left eyelid, indicating lesion of the facial nerve. Towards the end of the dissection, the external carotid artery was exposed; two ligatures were tied on it, and it was divided. The cavity was filled with cotton-wool. The operation lasted thirty-five minutes.

At the end of December the wound had healed, but the local paralysis remained. There was some swelling of the left side of the neck, indicating a return of the disease, which had been found on microscopic examination to be scirrhus.

A. HENRY, M.D.

ANDREWS ON DISLOCATION OF THE RADIUS AND ULNA OUTWARDS.—Dr. W. C. C. Andrews, of the Resident Surgical Staff of Bellevue Hospital, records the following case in the *New York Medical Record* for October 9. He says that it is one of the first, if not the first, of its kind reported by an American surgeon. Gustave S., aged seventeen, an engraver, was admitted to Ward Eleven on August 12, 1875. Two hours before, the patient fell from a shed (eight feet) on a manure-heap, which covered a pile of stones, and was about one foot thick. The patient said that he struck upon his right side, the right arm lying beside and partly under him—the elbow being straight or nearly so. The elbow must have been flexed at least 30° to allow such a dislocation without fracture of the olecranon.

Examination immediately after admission showed a very characteristic deformity. The forearm was at nearly a right angle with the arm, the hand resting upon the thumb in a position of forced pronation. The abrupt bulging of the forearm forwards and outwards was very marked. Both the biceps and triceps were uncontracted and flaccid. Externally the olecranon was easily felt, the finger slipping over its convexity and dropping into the sigmoid cavity.

This alone seemed to exclude fracture of the process; and the relaxed triceps, without any chip of bone in its substance, confirmed the supposition. Above, and to the inner side of the ulna, the round head of the radius was plainly felt, and rotated normally within the lesser sigmoid cavity when the hand was supinated. Projecting very strongly upon the inner side of the joint, and on a plane with the flattened posterior face of the arm, was the inner condyle. Both the epitrochlear process and the trochlear surface were distinctly felt, and the absence of fracture here was easily shown. The outer condyle lay deeply beneath the head of the radius, and could only be detected upon firm pressure. Indications of fracture were carefully sought for (both now and on other occasions), but could not be obtained.

The soft parts seemed to have escaped injury, excepting the capsular and lateral ligaments. There was but little swelling, no ecchymosis, and no appearance of rupture of muscles. The hand was warm, and did not feel numb nor sleepy. Good pulsation existed in both the radial and ulnar arteries. The arm was laid comfortably in an open wire splint, and lead and opium applied.

On August 13 the patient was thoroughly etherised to produce complete muscular relaxation. An assistant made counter-extension from the humerus, another grasped the forearm with his thumbs against the olecranon, the hand was then supinated and the forearm made nearly straight with the arm. Extension followed, during which the elbow was gradually flexed and olecranon pressed inwards, when both bones slipped readily into place. Very little force was used. Reduction was accompanied by the usual soft snapping between the articular surfaces. All the normal motions of the joint were restored and perfect, though somewhat loose. The head of the radius seemed very prominent and free in its movements, although it had always retained its natural relations to the ulna. The arm was replaced in a sling, and the lead and opium wash continued. The subsequent progress of the case presents nothing unusual. The patient left the hospital, with the motions of the part nearly perfect, on August 30.

DISEASES OF CHILDREN.

ULTZMANN ON ENURESIS.—At a meeting of the Medical Society of Lower Austria, Dr. R. Ultzmann made remarks upon the treatment of enuresis in children (*Allgemeine Wiener Medicinische Zeitung*, quoted in *Boston Medical and Surgical Journal*, February 10, 1876). Inability to hold the urine is not a rare occurrence in children. Boys are observed more frequently than girls with this affection, for the reason that the latter are more apt to conceal the fact. At first, owing to the weakness of the sphincter muscles, the discharge of fæces and of urine occurs without the experience of any sensation on the part of the infant. It is only after the tenth or twelfth month that any sensation accompanies the act; and we cannot properly speak of enuresis of a child under two years of age.

Urinary calculus is a frequent affection of childhood, and, as is well known, has its origin in the uric acid infarctus of new-born children, the small renal calculus descending into the bladder and there becoming the nucleus of a vesical calculus. This lithiasis, as well as cystitis, purulent pyelitis, polypoid growths, etc., can coexist with incontinence of urine; so that in these cases the urine should always be examined, in order, before making a diagnosis of enuresis, to exclude these other affections.

The disease in question can be divided into enuresis diurna and enuresis nocturna; and if it manifest itself day and night, Ultzmann calls it enuresis continua. It can make its appearance regularly or periodically. It is not confined, as asserted by some, to the scrofulous, rachitic, or to those affected by worms, etc., but is often found in children of healthy robust constitutions. Sleeping too soundly has been assigned as a cause; but only healthy children sleep long and continuously. Trousseau speaks of a too violent contraction of the neck of the bladder, others of a hyperæsthesia of the mucous membrane of the bladder.

According to Dr. Ultzmann's views, the cause is to be found in an absence of the proper relation between the detrusor and the sphincter muscles; the latter is weakened, and consequently the action of the former preponderates. At night, when volition ceases to exercise any control, this affection, when there exists a predisposition to it, manifests itself.

The treatment recommended is based upon this theory, and consists in measures to strengthen the sphincter muscle. The remedy employed, which is not alleged to be new, is the induced current, the method of its employment being a modified one. It was formerly the custom to apply one pole through the urethra to the prostatic portion, which is a very difficult proceeding with infants, owing to the narrowness of the urethra. This operation, however, is not always free from danger, and is, moreover, liable to cause urethritis or cystitis. The urine often becomes decomposed, and the patient is consequently made worse.

During the last two years Dr. Ultzmann has been in the habit of applying the induced current indirectly to the neck of the bladder by placing in the rectum or vagina a thin rod of brass, the end of which is connected with one pole, while the other is applied to the pubes or thigh. Each application lasts from five to ten minutes, and is made daily. The duration of treatment extends from four to six weeks.

Of nine cases thus treated (five girls and four boys) there was a decided improvement in all. The enuresis continua became in a short time a nocturnal one, and the enuresis diurna a periodical one. Four cases were completely cured. In four cases there was a relapse, but on resuming treatment recovery always followed. Of the nine reported cases three were brothers, respectively five, six, and eight years old. These three were much improved by the treatment.

The same treatment has proved very beneficial also in adults, especially in women when the incontinence has followed severe confinements, two such cases having come under treatment.

The good result of this treatment is explained anatomically by the fact that the nerves of the rectum are the hæmorrhoides medius et inferior, which come from the plexus pudendalis and sacro-coccygeus. These nerves supply also the bladder, and consequently the muscular contractility of the latter is thus excited.

Dr. Fleischmann remarked that he had experienced equally extraordinary results with this treatment in the case of a half-idiot boy who had a continual incontinence of both urine and fæces day and night. He recommended, however, that in the case of girls the metal rod be always introduced into the rectum, and not into the vagina, as there was no urgent necessity of placing it in the latter. With regard to internal treatment, he had seen excellent results from the use of belladonna. After the patient had taken from five to six grammes (four to five scruples) complete recovery had taken place, and no relapses. When, therefore, success did not follow the use of electricity, he recommended a trial of belladonna or strychnine.

Dr. Winternitz had observed a disappearance of this disease take place coincidently with an outbreak of eczema on the nates, and in addition recommended cold-water irrigation by means of Atzberg's apparatus.

MATERIA MEDICA AND THERAPEUTICS.

JACOBS ON THE TREATMENT OF DIABETES BY GLYCERINE.—In Virchow's *Archiv*, Band lxx. Heft 4), is an article by Dr. Julius Jacobs on the treatment of diabetes by glycerine. Various authors are quoted as having used this drug with good effect, and Schultze's theory of its action is alluded to, viz., that diabetics are deprived of their respiration material by the excretion of sugar, and are therefore obliged to consume their fat and protein compounds; but that when glycerine, which cannot be converted into sugar in the animal economy, is administered, carbonic acid and water are formed and respiration maintained without any calls upon the body-tissues. Two forms of diabetes are referred to; that in which a judicious diet is sufficient for a cure; and that in which neither medicine nor diet avail much. Of the latter kind, two cases are given in the paper, with tables of the daily analysis of the urine. Under the treatment by glycerine the patients are said to have remained perfectly free from the gastric and intestinal catarrh, and the resulting anorexia, vomiting, etc.

In the first case the diet was restricted to animal food, eggs, greens, chocolate, coffee, and tea. But the patient was allowed about five ounces of wheat

bread *per diem* during some part of the time. He was ordered Schultze's prescription, viz. glycerine 25 grammes, powdered tartaric acid 5 grammes, water 700 grammes in the twenty-four hours. The sugar decreased somewhat in quantity, but the specific gravity remained at 1050 to 1060. The body-weight remained stationary.

In the other case also the sugar undoubtedly diminished in quantity under the administration of the glycerine with a restricted diet. Dr. Jacobs, however, thinks that the improvement was not due to the latter, for that alone had failed on a former occasion to relieve his first patient.

The writer concludes that no remedies yet known can cure diabetes. Some can alleviate symptoms and prolong life. Glycerine is one of these, if its administration be persisted with. The grounds of his faith are these: that with its use the quantity of sugar and of urine excreted diminishes, the thirst lessens, and there is no diarrhoea; that the patient improves in general health; and that if he do not gain in weight he at any rate does not lose.

It is, however, stated with perfect candour that on each and all of these points Kulz, from the observation of other cases, has formed a directly contradictory opinion. The author lays some stress upon the fact that the specific gravity of the excreted urine varied inversely as the quantity of sugar. So constantly was this the case that he could say from the increase of the specific gravity that the sugar had decreased. The explanation given of this is that, by the administration of glycerine, the sugar is converted into something else of a greater specific gravity and giving no reaction with copper, and that this new substance being excreted by the urine keeps up its specific gravity.

[These two cases can hardly be taken to prove, as the author would appear to think, the value of glycerine in diabetes; and English physicians would, we think, be inclined to agree with Kulz. Dr. Pavy has found the remedy worse than useless, and the quantity of sugar increased under its administration. Moreover, that their specific gravity remained very constantly at 1060°, reaching in one to 1070°, would suffice to show that these cases were most exceptional.—*Rep.*] J. F. GOODHART, M.D.

ABRAMOWSKI ON THE ACTION OF THE FARADIC CURRENT IN ACUTE RHEUMATISM.—In the *Berliner Klin. Wochens.* for February, 1876, Dr. Abramowski records the results of experiments with the faradic current in fourteen cases of the disease. He made use of the electric brush, either placing the moistened positive pole on the sternum, and the negative pole, armed with the brush, on the skin of the affected joint, or connecting both wires with the galvanic circuit and placing their terminations lightly upon the joint at a constant distance of one centimètre from one another. For therapeutical purposes he always employed the former method. With regard to the electro-sensibility in rheumatism, he found that this was always increased over the diseased joints, in opposition to von Drosdek, who has stated (*Centralblatt für die Med. Wissenschaft.*) that the sensibility to the electric current is much diminished or almost lost. Therapeutically, the application of the induced current proved of great service. The diseased joints were faradised between ten and eleven in the morning; each sitting lasted ten to fifteen minutes, and the results were mostly noted at four in the afternoon.

By this time in many cases the pain was entirely relieved, so that patients who previously shrank from the slightest movement, were able to move the arms and legs freely. In other cases, from the notes appended, it would appear that relief was not so rapid, but it was seldom delayed beyond a day. The average length of time required for treatment by this method was ten days. The temperature rose and fell with the increase and diminution of the local symptoms, but no decided conclusions could be drawn from the cases as to the influence of the treatment upon the occurrence of cardiac complications. Though permanent improvement was obtained only after several sittings, the author is inclined to rate very highly the relief which almost always occurs, commencing soon after faradisation, and lasting at least some hours.

FÜRSTNER ON THE USE OF THE INDUCED CURRENT IN CERTAIN FORMS OF DILATION OF THE STOMACH.—In the *Berliner Klin. Wochens.* for March 13, 1876, Dr. Fürstner describes three cases in which the induced current was used successfully for the relief of distension of the stomach. The patients were all young females, aged respectively twenty-one, thirteen, and twenty. The first, without any evident hereditary tendency to nervous diseases, had been well till her seventeenth year, when she received a blow on the epigastrium, which was followed at once by intense pain, and somewhat later by a convulsive attack with loss of consciousness. The pain continued, the gastric region swelled, and frequent vomiting afforded no relief. After four days these symptoms subsided, but convulsive attacks recurred frequently and in the intervals there were headaches, and violent pains in the epigastrium. The fits were preceded or followed by the above-mentioned gastric symptoms, which often lasted several days, without, however, leading to any particular disturbance of the general health. When she came under notice, the abdomen was much distended, tense, and painful; and the lower convex border of the stomach was distinctly indicated on the surface of the abdomen about four-fifths of an inch above the navel. Convulsive attacks of a hystero-epileptic character were frequent during her stay in hospital, and were ushered in by a vague sensation of pressure and tenderness in the gastric region. No benefit was obtained from the use of ice, from morphia injections, or from washing out the stomach. A moderately strong induced current was then applied, one moist electrode being held on the left hypochondrium, the other placed over the stomach, and drawn with considerable pressure from cardia to pylorus. The result was constant: after a short time the swelling diminished, the pain ceased, and at the end of the proceedings the return of the stomach to its normal limits could be demonstrated by percussion. This distension did not recur for hours, sometimes not for days, and was always again easily reduced by the same treatment.

The second case was similar, the patient having fainted and struck her abdomen in the fall. On returning to consciousness she complained of burning pain in the stomach, and two hours later had her first convulsive attack, soon after which distension of the abdomen with repeated vomiting, occurred. The gastric symptoms recurred at irregular intervals either preceding, accompanying, or following the fits, often however appearing alone. She frequently vomited, and complained of an excessively tender

spot at the epigastrium. In the third case, again, a blow on the epigastrium caused intense burning pain, with vomiting, and distension of the abdomen, followed in the evening by general convulsions. The fits were repeated three times, on each occasion accompanied by gastric symptoms, and the patient, on admission, presented a condition similar to that observed in the second case. In the intervals of the attacks she suffered frequently from periodical headaches which she had had from childhood, and occasionally from left pleurodynia. In all three cases are to be observed the rapid development of hysterical symptoms from a blow, the periodical fits preceded by distension of the stomach, and the marked relief of the latter by faradisation. The author attributes the result to contraction of the walls of the stomach caused by direct, and not by reflex irritation; since in several patients, whose stomachs he artificially distended with carbonic acid gas, he found that the swelling was more easily reduced by the firm application of moist electrodes, than when the skin was more directly irritated by a dry metallic brush. He suggests the use of the induced current in other forms of dilated and distended stomach.

F. TAYLOR, M.D.

ROBERTS ON THE USE OF TURPENTINE IN TONSILLITIS.—In the *Philadelphia Medical Times* Dr. S. H. Roberts strongly recommends the external use of turpentine in tonsillitis. He applies it as follows. A flannel folded in four thicknesses is wrung out in hot water, and oil of turpentine poured over a spot about the size of a crown-piece. The flannel is then applied over the subparotid region and the fomentation continued as long as it can be borne. After its removal a dry flannel is applied, and turpentine rubbed over the same region every two hours. Dr. Roberts believes that turpentine has a specific effect in tonsillitis; he has proved that its action is not merely that of an irritant, by employing in its place mustard, croton-oil, tincture of iodine, etc., none of which had the effect of diminishing the inflammation of the tonsils which the turpentine had.

WHITTAKER ON HYPODERMIC ALIMENTATION.—Dr. Whittaker relates, in the *Cincinnati Clinic*, a case in which a patient's life was apparently saved by the hypodermic injection of nutrient fluids. The patient suffered from persistent vomiting and irritability of the rectum, which prevented any nourishment being retained in either the stomach or bowels, and death from exhaustion was imminent. Dr. Whittaker then commenced to administer beef-tea and milk hypodermically every two hours, in teaspoonfuls. These were continued three days, and then cod-liver oil was used in the place of milk. The patient improved rapidly and made a good recovery. The injections of milk caused small abscesses, but no inconvenience resulted from the use of the cod-liver oil.

BOMPART ON THE CURE OF TETANUS BY JABORANDI.—In *L'Union Médicale* for March 7 (quoted in *Paris Médical*, March 16) Dr. Bompert, of Vitry-le-Français, narrates a case of commencing tetanus cured by jaborandi. A woman aged sixty-two was operated upon for cancer of the left breast on December 26 last. On January 6 she had rigors, on the 9th dysphagia, which increased to very well marked trismus. It was impossible to make the patient take any solid food. The two most urgent indications were to feed the patient and treat the

tetanus. The first indication was fulfilled by means of clysters of eggs, broth, and wine; black coffee, and some spoonful of the *elixir alimentaire de Ducro*, (alcohol holding the soluble principles of meat in solution). For the tetanus M. Bompert had administered enemata of hydrate of chloral, which was immediately rejected and consequently produced no effect. M. Bompert attributes the cure to the action of jaborandi administered as follows: four grammes of the pounded leaves made into an infusion. The patient took the same dose daily from January 23 to March 3, at which date every symptom of tetanus had completely disappeared. The jaborandi produced very abundant salivation. Half a glass to a glass a day produced considerable perspiration.

DA COSTA ON SALICYLIC ACID IN FOUL BREATH AND OFFENSIVE EXPECTORATION.—In the *Medical and Surgical Reporter*, quoted in *Canada Lancet*, March 1, 1876, Dr. da Costa, of Philadelphia, recommends salicylic acid as a preventive of the foul breath and offensive expectoration of consumptive patients. He administers it in five-grain doses, with one drachm of glycerine in half an ounce of water, three times a day. He finds that it modifies the offensiveness of the breath to a very great extent, and also, though in a lesser degree, changes the offensive character of the expectoration. It is also useful in fetid bronchitis. The solubility of the salicylic acid may be increased by the addition of a little borax.

BURRALL ON A METHOD OF ADMINISTERING FLUIDS WHEN THE JAWS ARE FIRMLY CLOSED.—Dr. F. A. Burrall of New York (*New York Medical Record*, February 19, 1876), says a simple examination, which any one can easily make of his own buccal cavity, will show that posterior to the last molar tooth, when the jaws are closed, is an opening bounded by the molars, the body of the superior and the ramus of the inferior maxilla. If, on either side, the cheek be held well out from the jaw, a pocket or gutter is formed, into which fluids may be poured, and they will pass into the mouth through the opening behind the molars, as well as through the interstices between the teeth. When in the mouth they tend to create a disposition to swallow, and by this method a considerable quantity of liquid may be promptly given. Dr. Burrall has used this plan for some time with success, and quotes one of the cases. He does not find that liquids thus administered run into the larynx.

W. DOUGLAS HEMMING.

CRAIG ON CHLORAL AS A DRESSING FOR WOUNDS AND ULCERS.—In an article on the external uses of hydrate of chloral in the *Edinburgh Medical Journal* for February, Dr. W. Craig says that he has tried chloral extensively as an external application to wounds and abraded surfaces. He found as the result of experiments that a lotion containing from 5 to 15 grains of the hydrate of chloral to the ounce of water formed an excellent dressing to ulcers and wounds, dressed with lint and gutta-percha in the ordinary manner. He also used chloral solution as an injection into the sacs of large abscesses, and found that it tended much to diminish secretion and make the parts heal. He found it also an useful lotion for the eye in inflammatory conditions of that organ. It is an excellent application to burns, and very specially where there is a fetid discharge. He also found it a good application to remove warts

from the hands and fingers. He used for this purpose a lotion containing 15 or 20 grains to the ounce of water, applied by means of lint and gutta-percha. It causes no pain, and the wart speedily becomes smaller, and gradually disappears.

He also used it as a lotion to sore nipples and to inflamed mucous membranes. When chloral is applied to an ulcer, a wound, or to the interior of an abscess sac, it causes at first some smarting, but that only lasts for a few minutes, and is soon succeeded by a most agreeable sensation. Patients so treated have frequently told him that soon after the lotion was applied a very agreeable soothing effect was felt in the wound. Wherever there is a wound or ulcer there is irritability of the nerves of that part; and chloral, by soothing this irritability of the nerves, favours the healing process.

He has frequently used with good effect an ointment containing 30 to 60 grains of the hydrate of chloral to the ounce in eczema and other allied affections. He believed it to be one of the best applications in such diseases; and a medical practitioner lately told him that he had used it with marked benefit as a local application during an attack of erysipelas of the head. Chloral in various forms has been extensively used in the Edinburgh Royal Infirmary by Dr. P. H. Watson, who regards it as a valuable antiseptic, as active as carbolic acid or boracic acid.

SOLUTION OF BROMINE AS DRESSING.—The *New York Medical Journal*, for February, states that at the Bellevue Hospital a valuable stimulating application is obtained by dissolving two drachms of bromine in a pint of water. The use of bromine in a dilute form is rather a novel method, and it seems to offer some advantages.

DISLOCATION OF THE HEAD OF THE TIBIA FORWARD.—At the Roosevelt Hospital (*New York Medical Journal*, February) a rare case of dislocation of the head of the tibia has been under treatment. The injury was received by a force acting directly from behind. There was no fracture of the patella nor rupture of the ligament of the patella. The dislocation was readily reduced, and after a week the extremity put up in a water-glass bandage. Eight weeks after the accident the patient had so far improved as to walk about with but little difficulty, and with considerable motion of the knee-joint.

TREATMENT OF ACUTE RHEUMATISM BY PACKING WITH CARBOLIC ACID.—In the report of cases at St. Francis's Hospital in the *New York Medical Journal* for February, it is stated that several cases of acute rheumatism have been satisfactorily treated by means of packing with blankets wrung out of a very dilute solution of carbolic acid. The treatment is, in reality, a modification of the method practised at the Mount Sinai Hospital, and reported some few months ago. The method consists in adding an ounce of carbolic acid to a pailful of warm water, and saturating blankets with the solution before applying them. Marked relief follows the application.

TREATMENT OF DYSENTERY WITH SALICYLIC ACID.—The *New York Medical Journal* for February, in its notes of hospital practice, states that at St. Francis's Hospital cases of acute dysentery have been treated satisfactorily by means of doses of thirty grains of salicylic acid administered three

times a day. The only objection to the remedy appears to be a slight irritation of the stomach, but this is not sufficient to cause emesis.

TREATMENT OF METRORRHAGIA BY THE GALVANIC CAUTERY APPLIED TO THE INSIDE OF THE UTERUS.—A patient at the Mount Sinai Hospital (*New York Medical Journal*, February), developed persistent flow of blood from the uterus after an abortion, which was unsatisfactorily treated by all the ordinary agents. Persulphate of iron applied to the lining membrane of the uterus proved but of little benefit. Dr. A. Jacobi used the galvano-caustic apparatus, and found that after its use the metrorrhagia ceased. Previously to this the hæmorrhage had continued for eight weeks, and debilitated the patient to a marked degree.

TREATMENT OF BURNS.—At the Charity Hospital (*New York Medical Journal*, February), in the treatment of burns, when of a superficial character, a preparation consisting of two parts of collodion and one of olive-oil has been found to be very efficacious. When the burn is of an extensive character, gasoline proves of decided benefit. The advantage of gasoline is, that it is of the right consistence, and does not become rancid.

GELLÉ ON THE USE OF CHLORAL IN PRURITUS OF THE VULVA.—Chloral has been already recommended in pruritus of the vulva. Some facts mentioned by Dr. Gellé (*Tribune Méd.* December, 1875), give fresh support to this mode of treatment. M. Gellé has employed a solution of one in ten, as a lotion several times a day. A plug of cotton soaked in the solution can, as a further measure, be placed within the labia majora; the itchiness quickly becomes less, and at the end of a fortnight has completely disappeared.

DUQUESNEL ON THE PREPARATION OF POINTS OF TANNIN, ALUM, ETC.—The greater part of the points intended to be introduced within the cervix uteri are composed of a mixture of gum, bread-crumbs, etc., and certain medicinal substances. They possess, however, even after the addition of a small quantity of glycerine, a brittleness which is extremely inconvenient. M. Duquesnel (*Annales de Gynécologie*, January, 1876), uses gutta percha as a vehicle; the points are thus, when the temperature is slightly raised, rendered flexible, and are at the same time sufficiently tough and elastic.

An iron or copper vessel is to be heated over gas, and when raised to a temperature of about 100° Cent. equal parts of gutta percha, in small pieces, and the medicinal substance, viz., tannin, oxide of zinc, alum, etc., are to be placed in it. The two substances are intimately mixed, and, with the aid of glass or metal plates, are rolled into cylindrical form. When these points are in contact with numerous surfaces, they part with a portion of the medicated principle they contain.

PSYCHOLOGY.

VOISIN ON THE SUBCUTANEOUS INJECTION OF SHEEP'S BLOOD IN THE INSANE.—At the meeting of the Société de Médecine Pratique on November 13 (*Paris Médical*, February, 10, 1876), Dr. Voisin read a paper on this subject. The method of treatment is not directed against the mental state, but is intended to keep up nutrition in sufferers from melancholia considered as incurable. Dr. Voisin mentioned two cases in which sheep's blood was injected, both being women, one aged forty-nine, the other forty-four, and both suffering from hypochondriasis, delusions of persecution, riches, etc. In the first case fifty grammes of blood from the jugular vein of a sheep were injected into the subcutaneous cellular tissue of the arm. This was repeated every eighth day. According to Dr. Voisin, this method is recommended by Karst, and declared inoffensive by Landerberger, Poncet, and Ponza. It should be of use in patients whose cachexia is tending to a fatal termination. W. DOUGLAS HEMMING.

HITZIG ON THE AIMS AND OBJECTS OF PSYCHOLOGY.—In a published address entitled 'Ziele und Zwecke der Psychiatrie,' and delivered in the University of Zürich, Professor Edward Hitzig gives his opinions on several points which are subjects of controversy at the present day. The body of the address consists of an excellent view of the well-known causes which influence the onset, duration, and results of attacks of insanity, together with a statement of facts concerning lunacy, suited to a lay audience, and which, therefore, need not be noticed here.

The author thinks that civilisation more than atones for the extra strain of work and pleasure which she imposes, by the increased comforts and protection she affords to even the lowest of the people. Owing to the large proportion of cases of insanity which, though not incurable at first, rapidly become so if not cured, preventive measures are of greater relative importance in lunacy than in general medicine. Religious fanaticism is, too, regarded as a very frequent exciting cause of insanity; the consolations of true religion can harm none, and merit, instead of a lukewarm toleration, our highest regard; but as different as poison from medicine is fanaticism from religion. Numerous examples are

quoted where so-called religious movements have either arisen directly out of insanity or have rapidly led to it. It is especially on the hereditarily predisposed that such disturbing influences as the above are most potent for evil; hold constantly before weak minds the two dark themes of eternity and damnation, then present to them, as an antidote to the spiritual trembling you have caused, mystic sensational pictures of love, and beware what will become of the minds of your hearers.

With regard to consanguineous marriages, the author says that, provided the family be healthy, and admixture of fresh blood has previously regularly taken place, an occasional marriage of near relations is not productive of harm; but that if there be insanity in the family, the union of two branches, in each of which it has perhaps lain dormant, is exceedingly likely to cause a fresh outbreak. He also complains that medical opinion is not more frequently sought and acted upon as to the suitability of marriages. After dilating upon the evils of intemperance, Hitzig recommends that habitual drunkards should be detained under care and treatment for certain limited periods of time, especially after recovery from attacks of delirium tremens or other forms of insanity, that they may thus acquire greater strength of will to resist temptation in future, and that this proceeding should be sanctioned by law. He specially advocates the higher education of the people, the improvement of their homes that they may resort less to places of public refreshment, and the establishment of suitable institutions, where those who have no comfortable homes may pass their leisure hours. It is urged that psychological medicine should be made a compulsory subject of examination for all legal qualifications to practice, and that young medical men should be encouraged to spend limited periods of time as resident assistants in asylums before entering on general practice; also that stringent measures ought to be taken by the State to bring all cases of insanity early under treatment, with a view to curing a much larger proportion than obtains at present.

OBSTETRICS AND GYNÆCOLOGY.

STIEBELING ON A CASE OF PRESENTATION OF FOUR HANDS.—Dr. George C. Stiebeling, of New York, states (*New York Medical Journal*, February) that on November 4, 1875, he was called to see Mrs. M. S., aged twenty-four, secundipara. She had been in labour for about five hours. However, on examination, he felt through the bag of waters what later he could discern distinctly as hands. As the os uteri was dilated enough to allow the introduction of his hand, he resolved to perform version and extraction. On breaking the bag of waters, he met two hands, and going a little higher up in search of a foot he met two more hands. Soon he found two heads, one to the right, and the other to the left. He now got hold of a foot, brought it down without

difficulty, and extricated one child, a boy. The second one was delivered in the same manner, also a boy; both crying lustily. The mother and children did well.

BARKER ON THE DIAGNOSIS BETWEEN PELVIC HÆMATOCELE AND PELVIC CELLULITIS.—A clinical lecture by Dr. Fordyce Barker of New York, published in the *Richmond and Louisville Medical Journal*, for January, concludes with the following remarks on diagnosis. Pelvic cellulitis and pelvic hæmatocele both have their seat in the pelvic cavity immediately in contact with the uterus; in both there is the development of a tumour in the pelvic cavity; in both there is a certain amount of pelvic peritonitis, which results in uterine adhesions, and both originate in some predisposing disturbance of the uterus or its appendages.

While the two diseases have these marked features of resemblance, there are many symptoms radically different. Hæmatocele is usually associated with some catamenial disturbance, and in some rare instances with abortion; but never is the result of parturition. Cellulitis is frequently a disease of the puerperal period, or a consequence of abortion, or of any inflammation of the organs within the pelvic cavity. Hæmatocele is frequently ushered in or attended with uterine hæmorrhage. This rarely, if ever, occurs in connection with cellulitis.

In hæmatocele, the pelvic tumour is formed rapidly; that is, ordinarily in a few hours. In cellulitis, the development of the tumour is a process of days.

In hæmatocele, the tumour is, at first, yielding, elastic, and gradually becomes harder in proportion to the lapse of time from the period of extravasation. The tumour in cellulitis is hard in the beginning of its formation, and gradually softens. In hæmatocele, the formation of the tumour is the beginning of the disease. In cellulitis, it is the result of an antecedent inflammation. In hæmatocele, the tumour is distinct from the uterus; its volume is considerable; it displaces the uterus laterally and anteriorly, so that the os is directed backward. In cellulitis, the tumour apparently belongs to the uterus on one or the other side, and does not displace the organ in a marked degree. Finally, hæmatocele is ushered in by symptoms of nervous prostration and shock, and followed by those which attend pelvic and general peritonitis. Cellulitis begins with the general and local symptoms of inflammation.

RICHARDSON ON SUBACUTE CYSTITIS FOLLOWING PARTURITION.—In the *Boston Medical and Surgical Journal* for February 3, Dr. W. L. Richardson, of the Boston Lying-in Hospital states that during the past three years he has met with four instances of a marked inflammatory condition of the bladder following delivery. He believes it possible that many of the cases of metritis or circumscribed peritonitis which have been reported by physicians may have been a similar temporary affection of the bladder; and with the view of calling the attention of the profession to this variety of cystitis, he reports cases. He sums up with the following remarks. All these cases presented certain points in common. In all, more or less protracted pressure was exerted, during the progress of the labour, by the child's head upon the bladder. In two of the cases, the forceps was used to hasten the delivery. In two cases in which the cystitis was best marked from the outset, the invasion

of the disease was announced by a chill. In the first case, where there was a relapse of the disease, a second chill preceded the rise in the temperature and pulse. In all the cases there was great dysuria, which in most of them was the chief symptom complained of by the patient, apart from the general constitutional disturbance. In three of the cases there was marked tenderness over the region of the bladder, and the patients complained of more or less pain referred to the same spot. In one case the pain was so great as to render the use of morphia necessary. In the severer cases, more or less nausea and vomiting were noticed during the progress of the disease. The clinical history of the lochia and milk was normal from first to last. In all the cases, the urine contained a large amount of mucus and more or less pus. In only one case was blood found in the urine on a microscopical examination. In none of the cases was the constitutional disturbance as great as would naturally have been expected from the daily variation in the record of the temperature, pulse, and respiration. At the evening visits the patients complained of feeling feverish and sick, but in the mornings declared themselves almost well, except for the dysuria or the local pain and tenderness on pressure over the pubic region. The record of the pulse, temperature, and respiration was, in all these cases, very peculiar, being characterised by a low morning and a high evening range, and this peculiarity was especially marked in the first two cases. In the last two the same variation was noticed, but the differences recorded were not nearly so great as in the others.

The only treatment adopted was the application of poultices over the region of the bladder, until the pain and tenderness had in a great measure subsided; the administration of morphia, either in suppositories or by the mouth, for the relief of the pain or dysuria; and finally, after the more acute symptoms had subsided, the bladder was washed out with warm water, and later with a weak solution of carbolic acid and water. In all the cases the washing out of the bladder was followed by a relief, and by a sudden disappearance of all the symptoms complained of, that was very striking.

KEITH ON A CASE OF FIBRO-CYSTIC TUMOUR OF UTERUS; REMOVAL OF UTERUS AND OVARIES.—Dr. Thomas Keith relates the following case in the *Edinburgh Medical Journal* for March. Emily C., aged forty, a nurse, came to him in February, 1875, from Dr. Millar, of Londonderry, on account of a soft cystic uterine fibroid of rapid growth. Though the patient had been aware for more than a year that there was something wrong, Dr. Millar's attention had been called to the existence of a tumour scarcely two months before. Since then it had increased much. There were profuse discharges of blood at the periods, and frequent attacks of pain. She had lost flesh, and was unable to discharge her duties.

The tumour extended three inches and a half above the umbilicus. Between it and the edges of the ribs on the left side one finger could be placed; on the right side two fingers. It was prominent, movable to some extent, one day elastic and hard, the next day soft and flaccid; so much so that when seen in its state of relaxation, it might easily have been taken for an ovarian cystic growth. There was no bruit over it anywhere. The cervix uteri was not much enlarged. It lay far back, and un-

usually low in the pelvis. Movements of the tumour in any direction at once affected it.

Till recently, Dr. Keith had looked upon the removal of fibrous tumours of the uterus by abdominal section as unjustifiable under any circumstances. But, within the last few months, he had operated in two cases of fibro-cystic disease of the uterus, in one case supposing the tumour to be ovarian (the only error in diagnosis in more than two hundred operations); in the other, almost driven into operating by the dogged determination of the patient to have her tumour taken away. Both of these were miserably constituted women, worn out and emaciated, bad subjects for the simplest operation; yet both recovered, and are now well. After anxious thought, the removal of the uterus with the ovaries was advised and agreed to.

This was done on February 15. Sulphuric ether was given. An opening ten inches in length was made, and the tumour was slowly pressed out of the abdomen. Both ovaries came with it, well up on the tumour. The broad ligaments were very large, covered with great veins, and full of cysts between the layers on each side. Each broad ligament was secured separately below the cysts; then a strong steel-wire was passed round the thick neck of the tumour, immediately above the vagina, and firmly secured by Kœberlé's instrument. The uterus, ovaries, tubes, and masses of cysts in the broad ligaments were then cut away. As, at this stage, it seemed doubtful whether the cut cervix could be secured external to the peritoneum without too much tension on the vagina, a piece of thin India-rubber cloth was wrapped round the neck, and fastened by another *serre-nœud*, embracing also the two tied ends of the broad ligaments. A sort of tube was thus formed, separating the strangulated tissues from contact with the living. The intention was to let the whole thus protected drop back into the pelvis, leaving the India-rubber funnel to give exit to any discharges. It was found, however, just possible to secure the stump in the lower angle of the wound, though with no small tension on the posterior wall of the vagina, by passing two soft needles through it, and bending them at a considerable angle. Several bleeding points were secured by Lister's ligatures, and care was taken to prevent blood from getting into the peritoneal cavity. The omentum was drawn downwards, and spread over the intestines as far as possible into the pelvis. The wound was closed by silk and horse-hair sutures. The only dressing used was some folds of antiseptic gauze, covered by cotton-wool and a bandage.

The weight of the tumour some hours after its removal was eight pounds four ounces, but a large amount of serum had already oozed from it. This did not coagulate on exposure to the air. The uterine cavity was three inches in length, in addition to about an inch and a half included in the part secured in the wound. In neither of Dr. Keith's former cases was the cavity enlarged.

The operation lasted an hour. The anaesthesia with sulphuric ether was quiet and perfect. There was no vomiting during the operation or after it. In the afternoon, two opiate enemata (twenty and fifteen minims of laudanum) were given to quiet pain. By evening, there was moderate perspiration, also some refreshing sleep. A few turns of the screw were necessary to check some oozing from the stump, the surface of which was of the size of a five-shilling piece.

On the ninth day, an hour and a half after action of the bowels, sudden hæmorrhage came on from the wound. It was detected at once. On removing the bandage, the large pad of cotton-wool was soaked in blood up to the sternum, and blood was flowing in a stream over the pubes, forming a pile of clot between the thighs. Fortunately the patient was calm, the apparent coolness of the nurse preventing her from taking fright. The blood came from below and appeared at the surface, at the upper edge of the now hardened slough. Pressure and perchloride of iron were trusted to. For half an hour the bleeding broke out again and again in a most determined way, but by stuffing all round the slough with lint soaked in perchloride of iron, and making pressure with the fingers it was at last checked, though the hand was not removed for a couple of hours, when a compress secured by plaster took the place of the fingers. The patient looked exhausted, for the pulse had become rapid and feeble. A large opiate was given, and repeated at night.

On the fifteenth day, the slough came away in a mass with the wires, needles, and India-rubber protective. A deep cavity was left, into which the finger passed three inches. Upwards of an ounce of intensely putrid pus had collected behind the slough, which was found to have extended nearly an inch beyond the ligatures.

A rapid convalescence followed, and she returned to Londonderry, quite alone, thirty-two days after operation. She at once resumed her duties as nurse, taking charge of a heavy child; and though she wrote some months afterwards that she was stronger than she had been for years, she has since had an attack of acute rheumatism, from which she was convalescent at the time when the paper was written.

DERMATOLOGY.

RIZZOLI ON ONYCHIA ULCEROSA LURIDA.—In a communication to the Bologna Academy of Sciences (*Centralblatt für Chirurgie*, quoted in *Allgemeine Medicin. Central-Zeitung*, March 25), Dr. Rizzoli expresses the opinion that the term onychia maligna should be reserved for cancerous onychia; and that the term onychia ulcerosa lurida should be applied to the form specially described by

Vanzetti. Vanzetti alleged that the nail had nothing to do with either the origin or the continuation of the disease, and endeavoured to prove that it was sufficient to treat the ulcer by nitrate of lead to ensure recovery. Rizzoli, on the other hand, says that microscopic examination has shown him that the nail has many sharp projections on its under surface sufficient to keep up the ulcer; while nothing is found on examination of the ulcer itself capable of explaining its obstinacy.

In order to cure, therefore, it is necessary either to remove the nail or to protect the ulcer from its irritation. This protection is very well afforded by nitrate of lead, which forms a resistant crust. It is not, however, sufficient in all cases; and the removal of the nail becomes necessary.

In place of nitrate of lead, caustic potash, quicklime, acetate of lead, and especially finely powdered bromide of potassium, may be used. In many cases the onychia arises from a dyscrasia, such as scrofula; and in these internal medication is necessary.

Dr. Menzel, of Trieste, in reporting on this paper, states that he had had under treatment a case of onychia of nine months' standing in a child six years old, which resisted the repeated application of nitrate of lead and red precipitate; nor was the appearance of the ulcer improved after removal of the nail. The pain and ulcer were cured by the internal administration of iodide of potassium.

COLOMIATTI ON THE HISTOLOGY OF LUPUS.—In an article in the *Annali Universali di Medicina e Chirurgia* for November, 1875, Dr. Colomiatti arrives at the conclusion that for the present at least, lupus vulgaris may be regarded as including two species; true lupus and false lupus (pseudo-lupus). Lupus maculosus, nodosus, hypertrophicus, exfoliatus, exulcerosus, and serpiginosus, are not distinct species, but only varieties, which may be met with either in true or in false lupus, though with variations. The divisions into scrofulous lupus and syphilitic lupus are of more importance. These correspond to the pseudo-lupus of the anterior, or to cutaneous tubercle which assumes a lupous aspect on the face.

Dr. Colomiatti defines true lupus as a new formation, having a basis of connective tissue, manifesting itself in the form of large nodosities varying in size from a linseed to a pea or larger, originating in the corium and containing small nodules. These nodosities are formed of a network resembling that of the tissues of lymphatic glands, permeated by numerous blood-vessels and capillaries, and enclosing many colourless cells. In the nodosities the nodules are formed in the network already mentioned, the meshes of which are enlarged; for the most part they consist of epithelioid cells sometimes accompanied with giant-cells, neither of which, however, have any other relation to the network than that of contiguity; they represent advanced stages of the cells which, lying outside the nodules, merely line the fibres and the fibrillary fasciæ of the network.

He regards lupus as essentially distinct from tubercle; the only points of resemblance being the nodular form of tubercle, and the existence of nodules in the nodosities of true lupus. The giant-cell, found in both, he does not regard as having any specific character, inasmuch as it is met with in very various circumstances. A. HENRY, M.D.

KAPOSI ON THE ETIOLOGY OF HERPES ZOSTER.—Dr. Kaposi (*Wiener Medizin. Jahrbücher*, 1876, Heft i.) describes the case of a man, aged fifty-four,

who was brought into the Vienna Hospital on October 21, 1874, to be under Professor Dittel's care for stricture of the urethra. A false passage had been previously produced. On the 25th he was feverish, had an eruption of herpes on the under lip and chin, and at the same time became affected with herpes zoster lumbo-inguinalis of the right side. The herpetic patches extended from the spine to the symphysis pubis. He had rigors on the 27th, and died on November 1. There was erysipelas of the scrotum and right groin. The bladder had been punctured above the symphysis for retention. The spinal ganglia of the last dorsal, and fourth and fifth lumbar nerves of the right side, were slightly, and the first, second, and third lumbar ganglia much swollen, and adherent to the surrounding tissue. The microscopic appearances to be described were observable in the ganglia of all these nerves, but were most marked in those of the second and third lumbar nerves.

The blood-vessels were distended by red corpuscles, and masses of corpuscles were lying free around the vessels and between the ganglia.

In some of the ganglion-cells there was pigment, which, from its amount, and in comparison with the appearances seen in the cells of the unaffected ganglia, was considered to be pathological. In other cells the protoplasm had retracted from the capsule, leaving a free space. The space within the capsule was in several instances found full of blood-corpuscles. In some cells the protoplasm had lost its granular appearance, and had become transformed into a homogeneous colourless mass, which did not stain in carmine. In this mass a shrunken nucleus was sometimes seen.

There was nothing pathological found in the connective tissue of the ganglia.

Professor Kaposi believes these pathological changes in the ganglion-cells to have been in this case the cause of the herpes, but does not infer that in every case identical changes must exist. A complete and valuable account of all the information which has been obtained regarding the pathology of the disease is given in the paper.

LANG ON THE HISTOLOGY OF LUPUS (WILLANT).

—Dr. Edward Lang, Professor of Dermatology at Innsbruck, believes (*Wiener Medizin. Jahrbücher*, 1875) that the first stage of the morbid process in lupus is constituted by a network of cells (lupus-cell network) which grow outwards from the wall of the blood-vessels and lymphatic vessels. From the branches first formed other branches take their origin, which meet and anastomose with each other, the network becoming larger and its meshes smaller. The process occurs in two forms. In one the diseased part is not sharply bounded, the cell-growth extending into the interstices of the adjoining tissue; in the other, the affected part is limited by a boundary of normal structure, in which there are concentric layers of small spindle-cells. The first he calls the infiltrated, the second the localised form.

In the infiltrated form, the irregularly branched cells assume more and more the appearance of granulation-cells, and after a considerable time undergo a process of degeneration which frequently begins about the centre of the mass. In the localised form, the cells soon begin to degenerate. The cells in the centre alter first, both the cell and the nucleus sometimes swelling to double their original diameter.

The swollen cells resemble epithelial cells. There are also cell-masses formed, which contain a great number of nuclei. The cellular masses are in communication with the lupus-cell network. In a further stage these cells have broken up into small particles.

Groups of localised lupus-nests run together and form larger lupus-masses, some breaking down whilst new ones form. Near the border of the lupus-formation, there is a proliferation from the wall of the vessels of a system of tubular structures which contain no formed elements, although they are evidently connected with the process of circulation.

As the process advances, the vessels disappear under the compression produced by the growing cell-network, the elements of the vascular wall undergoing the same kind of degeneration as the cells of the network. At this stage there are also found structureless colloid flakes.

Similar changes are seen in the infiltrated form.

Proliferation of the sweat-glands and their ducts takes place, followed by a degeneration in the form of multinucleated masses. Precisely similar changes take place in connection with the sebaceous glands.

From the cells that are formed in the corium processes enter the rete Malpighii, separating the epithelial cells from each other. A moderate amount of this infiltration produces a succulent condition of the epidermis. When largely developed, the free cells and detritus produce crusts on the skin. In other cases, when the cells grow rapidly, the epidermis is bulged outwards, becomes thinner, and often yields. He never observed a transformation of the epithelium into lupus-tissue, nor a passage of one kind of cells into another.

Corpuscula amylacea were sometimes found in the centre of the multinucleated masses.

In skin from a cicatrising lupus, the cutis was found to be formed by closely felted connective tissue, which contained *corpuscula amylacea*, but no multinucleated masses. There were few blood-vessels, and from these there was a development of lupus-cell network.

In a second paper on the same subject (*Mediz. Jahrb.*, 1876, Heft i.), the author discusses at length the nature of the multinucleated masses which he believes to represent an intermediate stage in the process of degeneration of the tissues. In different instances he recognised them as parts of blood-vessels, sweat-glands, sebaceous glands, hair-follicles, and finally as large masses containing nuclei, arranged in planes which crossed each other.

These disintegrating masses he believes to be identical with similar structures which have been described as 'giant-cells,' and, after a critical examination of the facts and arguments which have been adduced in support of the views that have been held regarding them by different authors, contends that 'giant-cells,' wherever found, are nothing else, and have no other origin.

In a case of lupus in which a rhinoplastic operation had been successful, the skin being taken from the forehead, lupus-tubercles were two years afterwards found in the new skin.

[In regard to the nature of the lupus-cell network described as proliferating from the wall of the vessels, it is well to remark that Professor Lang does not indicate in these papers what his views are regarding the cells of the corium. It is to be inferred from his drawings and the text, that what he describes as a cell is the connective-tissue-corpuscle or plasmatic cell of Virchow, and the appearances described as

proliferation and extension of cell-processes should be interpreted accordingly.—*Rep.*] G. THIN, M.D.

RECENT PAPERS.

Treatment of Pityriasis Capitis by Chloralised Solutions. By Dr. Martineau. (*La France Médicale*, February 16.)
The Etiology of Leprosy. By Dr. Neumann. (*Allgemeine Wiener Medizinische Zeitung*, March 7.)

OPHTHALMOLOGY AND OTOLOGY.

JONES ON ENUCLEATION OF THE EYE.—In a paper in the *Dublin Journal of Medical Science*, for February, Dr. Macnaughten Jones states that he has arrived at the following conclusions in reference to enucleation of the eye after injury. If a globe be disorganised by an injury, shrunken, chronically congested, staphylomatous, in whole or part, or be subject to recurrent attacks of choroid-iritis; if it have any pus contained in it or be threatened with ophthalmitis; if any of these states have been complicated with hæmorrhage into the vitreous humour; and, above all, if the eye be painful, it is, he believes, safer to remove it, and not to wait for signs of sympathetic irritation in the fellow eye. This is the more to be insisted on in the uneducated and stupid patient, who may live a long distance from skilled advice. If a globe be penetrated by a foreign substance and contain it, enucleation is immediately indicated. If a globe have been injured, and we be uncertain of the presence of the foreign body, but that it is of such a nature as that it might enter and leave but a small external wound—as a piece of glass, a grain of shot, a portion of cap, a fragment of steel—we must be guided by the presence or absence of such symptoms as may follow a severe injury when no foreign body can have entered, and as, in the first case, enucleate on their appearance or persistence. While pursuing an expectant plan, we may, in great part, be helped to the conclusion as to the presence of a foreign body: 1. The nature of the accident and the character of the substance; 2. Clouding of the media, hæmorrhage into the vitreous body, prolapse of the iris, injury to the lens; 3. Formation of pus in the globe; 4. Considerable increase or diminution of tension; 5. Complete loss of vision; 6. Sympathetic symptoms in the other eye.

LORING ON DETERMINATION OF THE REFRACTION OF THE EYE BY MEANS OF THE OPHTHALMOSCOPE.—Dr. Loring publishes this year a monograph of sixty pages on the above subject. His name has been so closely connected with this subject for some time past, that one turns each page with the hope that something new will be found. But it is not so. He describes several ophthalmoscopes, giving the preference to his own, Knapp's, and Wecker's, and describes modifications which he seems not to know were proposed in England as far back as the beginning of 1873. After describing his last modification, consisting of a disc containing twenty-five correcting lenses, it is strange to find the following sentences: 'The disk can be rotated either with or against the sun, and can, if occasion require, be turned by means of the forefinger without removing the instrument from the eye. This is, however, of

little or no practical importance, as the observer is apt to become confused, and the patient unduly fatigued from the continuous glare.' Surely in a large clinic the ability to examine an eye 'without removing the instrument from the eye' is of importance. He does not agree with those who have objected to the use of two correcting lenses behind the mirror, and says 'the lessening in illumination is so small as to be of no consequence at all.'

Perhaps the most interesting question on which he speaks is that of our ability to test by the ophthalmoscope the total amount of hypermetropia present without using atropine. Mauthner says the total amount is revealed; and Loring, without accepting Mauthner's statement unreservedly, nevertheless believes 'that a very close approximation to it can almost invariably be obtained.' One of Mauthner's cases was the following. 'A boy of twelve years presented the usual symptoms of asthenopia. Both concave and convex glasses were declined for distant vision. Even convex one-sixtieth was obstinately rejected. The ophthalmoscopic examination brought to light a hypermetropia of one-fifth. The eye was then paralysed with atropia, and the total was found to be by glasses one-fifth.' Dr. Loring goes on to say: 'Inasmuch as I have never seen a case of total hypermetropia of so high a grade as one-fifth where there was no manifest at all, I am unable to corroborate the above case with a precisely similar one from my own practice. I could, however, cite many where the degree of the manifest was very trifling in proportion to the total revealed by the ophthalmoscope, and where the latter obtained by this means differed but slightly from what was subsequently obtained by the use of atropia and glasses. For example, one-thirty-sixth with glasses, one-twelfth with the ophthalmoscope; one-twenty-fourth with glasses, one-sixth with the ophthalmoscope, one-sixth with atropia, one-eighteenth with glasses, one-sixth with the ophthalmoscope, one-fifth and a-half with atropia; one-eleventh with glasses, one-fourth and a-half with the ophthalmoscope; one-twelfth with glasses, one-fifth with the ophthalmoscope, one-fifth with atropia, etc. Such glittering results as these certainly need but little comment, and their practical application but little explanation, the only wonder being that examinations of this kind are not as universal as the use of the ophthalmoscope itself.

'There is one point which at first appears curious, and that is, that we get the most exact, and certainly by far the most brilliant results, just where we should expect them least; that is, with the highest grades of hypermetropia, at least such has been the writer's experience; so much so that he feels convinced that it is very difficult, sometimes impossible, with young people to tell the lighter degrees of hypermetropia (less than one-fortieth) with the ophthalmoscope, unless, indeed, atropia has been used. This he believes to be owing to the fact that hypermetropes of a high degree often relax their accommodation entirely while looking inattentively into the distance, and make no effort to call forth their accommodation till their attention is aroused; when, however, their attention is called to some particular object, they instinctively call forth that amount, or very near it, which is demanded for parallel rays. Consequently, under glasses where particular attention is required of them in deciphering the smaller letters of the test card, they refuse to relax their accommodation except to a trifling degree. But when placed in a dimly lighted room, and told to look at a wall which offers

a black and diffused surface, and which will appear to them but a little less distinct even when seen in circles of dispersion, they have no difficulty in relaxing their accommodation. But young persons who have say hypermetropia one-fortieth, or less, see clearly in the distance with so little effort, that they probably never relax their accommodation, preferring to make slight demands on their ciliary muscle, than to see in circles of dispersion. Their condition is practically emmetropic, and in the ophthalmoscopic room they relax their accommodation no more than they are accustomed to, accommodating for the plane of the wall which they see distinctly, or at most for parallel rays. We may, however, lay it down as a rule even in these cases, that where little or no hypermetropia can be detected either by glasses or the ophthalmoscope little or none exists. . . .

'So much for the ophthalmoscope where atropia has not been used, but there are cases in which it is even superior to the test by atropia and glasses, where the latter, indeed, utterly fail in giving an idea of the amount of hypermetropia, as the following case will show.

'A bright little girl was brought to me for the purpose of having the exact optical condition of the eyes determined. With a convex one-twenty-fourth vision was decidedly improved; amounting, however, even with the glass, only to one-fifth of the right eye, one-tenth in the left. The same result was obtained under atropia. Glasses of various strengths from one-twenty-fourth to one-twelfth were tried, and still the vision remained about the same. Recourse was now had to the ophthalmoscope, when a total hypermetropia of one-seventh was found in the right, one-sixth in the left eye. The discrepancy between the glass selected by the child, and the amount of hypermetropia as given by the ophthalmoscope, was so great that an independent examination was made by another oculist with precisely the same result in each eye.'

W. LAIDLAW PURVES.

CRITCHETT ON CONGENITAL CATARACT AND ITS TREATMENT.—In an elaborate paper read before the ophthalmological section of the Brussels Congress in 1875 (*Annales d'Oculistique*, November, December, 1875, and *British Medical Journal*, March 4 and 11, 1876), Mr. Critchett discusses at some length the various methods of dealing with that form of cataract known as 'laminar' or 'zonular,' at present in vogue. At the outset he warned his hearers that surgical interference with cataracts which are complete, and which are met with in very early infancy, is not always safe or attended with good result, inasmuch as the opacity of the lens is in some instances indicative of an unhealthy fundus, a condition of things which cannot be predicted. In these cases, however, sight, or at least useful sight, has never been known by the patient, so that, however disappointing the result of an operation may be, the patient's actual condition is in no way worse thereby.

In cases of laminar cataract, on the other hand, the conditions are far otherwise, for experience has abundantly shown that a transparent margin of the lens may exist sufficiently wide to admit of very useful sight, so that individuals with this form of cataract have been known to complete their education and to have earned their living in spite of their defective vision. The question here arises, and was, in fact, addressed to the Congress, how far has this kind of laminar opacity a tendency to remain

stationary or to involve the entire lens. In Mr. Critchett's experience, cases in which there has been no irregular opacity of the capsule, as well as the opaque zones, have appeared to remain stationary; and a great improvement of vision has been obtained by the performance of an exceedingly small iridectomy, by which a portion of the pupillary margin only of the iris has been removed. This proceeding would, however, be applicable to such cases only as those which presented a considerable margin of transparent lens. The propriety of performing it instead of removing the entire lens would be, in a great measure, determined by the amount of improvement in vision which was obtained by the use of atropine. Assuming, after this had been tried, that it was deemed advisable to remove the cataractous lens, Mr. Critchett raised the further question as to whether it is safer to trust to the process of absorption alone, or to combine it with 'linear extraction,' with or without suction. His own experience had taught him that it was safer to trust to the removal of the lens by absorption only, for, although the proceeding involves loss of time, yet it is usually followed by the formation of a round and mobile pupil, whereas linear extraction will very often fail to procure this, and it is besides not unfrequently attended with considerable risk in its performance. Of course cases frequently occur to everybody in which linear extraction is imperatively called for. Under no circumstances, however, would Mr. Critchett operate upon both eyes at once, inasmuch as in the case of adults some useful amount of vision very often remains in the untouched eye.

BOWATER J. VERNON.

BEZOLD ON SALICYLIC ACID IN AURAL DISEASES.—The *Gazette Hebdomadaire de Médecine et de Chirurgie* for February 25, 1876, gives an abstract of some observations by Dr. Bezold in the *Monatsschrift für Ohrenheilkunde*, nos. 3, 8, 9, 1875, from which it appears that that gentleman has used salicylic acid in many diseases of the ear. He finds that the substance succeeds very well as a parasiticide and rapidly destroys oto-mycosis. Perforations of the membrana tympani cicatrise very rapidly when treated with salicylic acid injections. The acid also arrests the development of the germs of gonidia, but it is important to continue its use until all germs of the parasite have been extracted from the ear by injections. In suppurative inflammations, whether acute or chronic, good results have been obtained by the employment of an alcoholic solution of salicylic acid injected into the ear, the purulent secretion markedly diminishing and cicatrization advancing rapidly.

CHISHOLM ON SALICYLIC ACID IN AURAL DISCHARGES.—In the *Western Lancet*, no. 10, 1875, is an account of Dr. Chisholm's experience of salicylic acid in aural discharges. The form in which he used the acid was chiefly in powder diluted with calcined magnesia or oxide of zinc; the pure acid might, however, be applied quite safely to a discharging tympanic membrane. The powder, in the proportion of one part of salicylic acid to two parts of magnesia, is blown into the ear through a quill or a laryngeal powder-blower, the organ having of course been first thoroughly cleansed. Dr. Chisholm has found the effect good in all cases; its effect being, however, more marked in some persons than others.

REPORTS OF FOREIGN SOCIETIES.

IMPERIAL ROYAL SOCIETY OF PHYSICIANS IN VIENNA.

January 7.—*Double Paralysis of the Upper Limbs.* In a communication on this subject Dr. Rosenthal said that, in clinical experience, myelitic foci in the cervical portion of the cord are found to produce paralysis, first of the upper, and then of the lower, limbs. The same thing occurs in acute injury of this part, also when tubercle is present, and when the cervical spinal cord is compressed by extravasation. To the paralysis, contraction of the muscles is subsequently added. Isolated paralysis of the upper limbs occurs also when there is merely disease of the cells of the grey substance of the cord; and, according to almost all observers, the essential paralysis of children is due to acute disease of the anterior cell-groups of this part. This affection may also occur in adults. A third kind of isolated paralysis of the upper limbs, also produced by disease and subsequent degeneration of the anterior cell-groups of the cervical spinal cord, occurs in progressive muscular atrophy. Here also the paralysis is for some time confined to the upper limbs. Along with these central diseases there are also paralysis of the upper limbs arising from peripheral causes, such as effusion of blood between the roots of the nerves, pachymeningitis in the cervical portion of the cord, and pressure on the roots of the nerves in the affection described by Charcot as hypertrophic cervical meningitis. The author related two cases showing the importance of diagnosis, inasmuch as recovery occurred in them, which is not the case in myelitic disease of the cervical part of the cord.

January 14.—*Internal Strangulation.*—Dr. Klob made a communication on this subject. He could not well see why surgeons abstained from opening the abdomen in cases of internal strangulation. Ovariectomy was a dangerous operation, and yet had been successful in a large number of cases. To find the seat of incarceration is often very difficult, even in the dead body; and hence it is necessary to learn a methodical proceeding which may facilitate the discovery of the lesion. Such a proceeding is demanded by what is known of numerous cases, and surgeons will be able to perform the operation if only sufficient clinical and pathological material be afforded. The author was so convinced of this, that he would have abdominal section performed on himself if he suffered from internal strangulation. Ac-

cording to Rokitsansky, internal incarceration is produced by numerous but not always present peritoneal folds, by contracting false membranes, which form sacs, into which an empty portion of intestine passes, and cannot escape from the narrow opening when it has become filled. If the edge of the sac be rigid, we have transition from internal incarceration to internal (strangulated) hernia. Rokitsansky distinguishes three kinds of strangulation in internal incarceration. In the first kind, the pressure on the intestine is produced by another portion of intestine or of the mesentery. Generally it is the very movable small intestine that presses on the descending colon, or on the sigmoid flexure, especially when the former is over-distended and its innervation impaired, and the latter are empty and lie along the sacrum and pelvic wall. Most of the cases of internal incarceration of this kind occur in aged persons, who have a long mesentery, and suffer from habitual constipation through defective innervation. In them the incarceration takes place slowly and gradually. Rokitsansky relates in his work four cases of this kind in which the sigmoid flexure, the cæcum, and the ascending colon were compressed and rendered quite impervious by convolutions of the ileum. Dr. Klob had also had two cases. In one, a man aged sixty, the subject of habitual constipation, died with symptoms of meteorism, vomiting, ileus, etc.: the small intestine had rendered the descending colon quite impervious. In the other case, a man aged seventy-nine, also habitually constipated, died with similar symptoms, and the appearances found after death were quite analogous to those in the former case. The gall-bladder was contracted and contained a large calculus. With respect to this, it is worthy of remark that in two of Rokitsansky's four cases gall-stones were found; in the others, there is no mention of the state of the liver, though there was a want of biliary colouring in the fæces. In cases of this kind, nothing is to be expected from operation. The second kind of internal strangulation is that arising from twisting of the intestine on its axis. If a portion of intestine be so twisted, a half turn is sufficient to obstruct the large intestine. The axis on which the twist is made may also be the mesentery or another portion of intestine. The author saw two cases in which the sigmoid flexure passed over the liver, giving rise to a tympanic percussion-sound and leading to a wrong diagnosis. Internal incarceration of this kind is distinguished from the former by its rapid and sudden occurrence, and by the early appearance of peritonitis. A third kind of internal strangulation is produced, according to Rokitsansky, when bands, the results either of defects in formation or of disease, form rings or clefts. The vermiform appendix, the appendices epiploicæ, the appendages of the female genital organs, and new formations adherent to portions of the small intestine, give the opportunity for strangulation. In cases of this kind, reduction may be easily effected during life. With regard to the treatment of internal incarceration, it is worthy of remark that, in his work published forty years ago, Rokitsansky pointed out the inutility of internal remedies. Laxatives are useful at first, but do harm afterwards; the knife alone can then bring incontestable aid. Dr. Klob showed a preparation in which a band passing from an appendix epiploica of the large intestine encircled a portion of the ileum, contracting it, and leading to gangrene.—Dr. Schrötter said that four years ago he had con-

sulted Professor Rokitsansky in a case of internal incarceration in his clinic. An operation was performed. Although prepared to meet with difficulty, he was greatly astonished at the pressing forward of the intestine and the trouble of keeping it in place. He removed the obstruction, which was produced by about two inches of the sigmoid flexure being twisted on its axis and also compressed by intestinal convolutions. The result was unsuccessful, and he was blamed for performing the operation; but he held the same opinion as to its propriety as he had four years ago. In his case the operation was not decided on until the fifth day, when the intestine was gangrenous and perforation imminent.—Dr. Winternitz commented on the tendency of surgeons to delay operation until all other means had been tried. A proceeding which had produced remarkable results in many cases of internal strangulation was irrigation of the intestines. The intestine could receive large quantities of water (from one to three litres); he had seen a case in which simple injection of water succeeded after all other means had failed. In cases where the large intestine was twisted on its axis, as well as in intussusception, for the purpose of diagnosis, this treatment was to be recommended. It had been ascertained that the water passed up as far as the ileo-cæcal valve.—Dr. Klob admitted the possibility of a good result from injection of water; but he had met with two cases in which it had been used in vain, and had distressed the patients, who could scarcely bear the position on their knees and elbows. Besides, what good could injection do where, perhaps, the incarceration was produced by bands of false membrane?—Dr. Winternitz replied that injection could be performed when the patient lay on the back with the sacrum raised. It was of use also in the diagnosis of intussusception, tumours, etc.—Dr. Weinlechner related a case in which he had performed abdominal section on a child on account of intussusception in the ascending colon. The child died of peritonitis. A student also died of intussusception, on whom tobacco-clysters, injection of water, etc., had been tried without effect. He was already delirious when Dr. Weinlechner saw him, and therefore an operation was not performed. The necropsy showed that an operation might have been successful. In many other cases the symptoms passed off, and the patients recovered. His experience taught him that frequently the favourable moment for operation was lost while internal treatment was being pursued.—Dr. Eisenschitz had treated the first case mentioned by the previous speaker, and was then convinced that operation alone afforded a chance of life. The release of the intussuscepted portion of bowel was easy; adhesion did not prevent it. English surgeons had found no adhesions even after five or six days. In England, cases of recovery after operation for intussusception were not rare. Hutchinson had called attention to the danger of puncturing the bowel, and so allowing the escape of its contents into the peritoneal cavity.—In reply to a question of Dr. Teleky regarding examination by the rectum according to Simon's method, Dr. Dittel said that the proceeding was difficult to the operator and dangerous to the patient, besides being almost useless in cases of internal incarceration, as the hand could scarcely be introduced sufficiently far.

January 21. *Surgical Communications.*—Dr. Dittel showed the broken end of a meerscham cigar-

holder which he had removed from the bladder of a woman forty years old. The patient was said to have already removed a similar portion. Symptoms of cystitis set in, but soon disappeared. He also showed a pointed prickly piece of bone which, after passing through the whole intestinal canal, had become fixed in the rectum, from which it was removed; also a fibro-cartilaginous mass removed from the external ear, and a fragment of a catheter taken from the bladder.

Intra-articular Injuries of the Knee-Joint.—

Dr. Dittel had made experiments on the dead body, in order to ascertain what ligaments are stretched in normal and in powerful excessive movements, and how and where, in the latter case, intra-articular injuries are produced. The experiments had reference to flexion, extension, and rotation. *a. In flexion*, the anterior part of the joint was strongly put on the stretch, and this remained the only result when flexion was made as powerfully as possible. When the part was opened, no lesion was found. Besides the resistance of the ligaments, resistance was also afforded by the soft parts; on removing the latter, and bending the joint, it was found, on laying open the capsule, that the anterior crucial ligament was loosened, but not torn; and the loosening always occurred at the femoral insertion. If flexion were increased by insertion of a wedge the ligaments were completely torn off. The latter injury might occur in gymnastic exercises, and the intra-articular lesion might be recognised if the limb could be freely bent before inflammation set in. *b. The second series of experiments* had reference to normal and excessive *extension*. It was found that no amount of extension in a straight horizontal line produced intra-articular injury, but when the angle of extension was obtuse, the cartilages of the tibia were separated in young subjects, and the anterior crucial ligament was detached from its femoral connection. *c. Rotation* while the limb was bent, whether inwards or outwards, only stretched the ligaments. If rotation were attempted to be carried to a greater extent by inserting a piece of wood between the tibia and fibula, the latter bone was fractured or a complete breaking up of the joint was produced. A case had come under Dr. Dittel's care, of injury of the knee which had hitherto been produced only by experiment. A man, aged twenty-five, was on November 25, according to his account, turned out by a tavern-keeper, and fell to the ground. The next day the knee was swollen and somewhat warm; the skin was of usual colour, and movable. The swelling was sharply defined; fluctuation was evident; motion was difficult and painful. It was believed that there was extravasation in the joint; a puncture was therefore made, and a large quantity of dark fluid blood removed. Moderate compression was made, the limb was placed in a straight splint, and cold dressings were applied. On the 24th a second puncture was made, which gave exit to much fluid blood; and on the 29th another puncture was made. Severe inflammation of the joint with lymphangitis now set in, and the capsule was laid open and drained from both sides. Lister's dressing was used. The pus became thin and of bad odour; there were also symptoms of embolism, vomiting, great restlessness, etc., for five days. On the eleventh day there was suppuration in the thigh, which was treated by incision. On the thirteenth day, distinct crepitation was felt on rotating the joint. Amputation was performed under the carbolic spray, and Lister's

dressing was applied. The wound assumed an unhealthy aspect, the patient became greatly weakened, bed-sores appeared at several parts, and he died five days later. The necropsy showed that the anterior crucial ligament was torn away, along with the intercondylar eminence and an adjacent portion of bone. It was probable that feeble adhesion had taken place and had afterwards been broken through. As regarded the treatment of such cases, the most important part was to render the joint perfectly immovable, which was best done by a plaster of Paris bandage. Had this been done, the result of the case might have been more favourable.—Dr. Jurié had under his care a case in which he had opened the knee-joint according to Lister's method. It was doing extremely well.

January 28. *Trichiniasis*.—Dr. Heschl gave an account of three cases of trichiniasis which had occurred at Raabs, and called attention to the importation of trichinised pork into Vienna. Rats frequenting the neighbourhood of the place where trichinised pigs were kept were found to be affected with trichinæ.

Anatomical and Pathological Preparations and Casts of the Membrana Tympani.—Dr. Politzer showed a number of preparations which he had made for the exhibition in Philadelphia. His object was to show at a glance the anatomical relations of the parts, and especially the position of the membrana tympani, ossicles, and labyrinth. The normal preparations showed—1. The outer and inner surfaces of the membrana tympani with the ossicula auditus; 2. The bony meatus entirely separated from the surrounding bones, showing the oblique position of the membrana tympani; 3. Vertical and horizontal sutures of the ear, showing the Eustachian tube, cochlea, and vestibule from various aspects; 4. The relation of the semicircular canals to the tympanum; 5. The position of the cochlea with relation to the tympanum; the cochlea being in some of the preparations laid open to show the lamina spiralis; 6. Various views of the different parts of the ear in connection. The pathological preparations were: 1. Calcareous deposits in the membrana tympani; 2. Double perforation of the membrane; 3. A very large perforation, the membrane being almost entirely destroyed; 4. Funnel-shaped growth of the membrana tympani to the inner wall of the tympanum (rare); 5. Separation of the handle of the malleus from the membrana tympani (rare); 6. Extensive calcareous and cicatricial degeneration of the membrane, and growth to the inner wall of the tympanum; 7. Adhesion of the membrana tympani to the inner wall of the tympanum in such a way as to close the tympanic opening of the Eustachian tube; 8. Destruction of the membrana tympani and growth of the lower end of the handle of the malleus with the promontory. Dr. Politzer also showed casts of anomalies in the arching and of solutions of continuity of the membrana tympani. He called attention to the importance of a knowledge of the state of the membrana tympani with reference to diseases of the organ of hearing, and especially of the middle ear. Beginners met with great difficulties in discerning changes in the convexity of the membrana tympani and certain forms of solution of continuity. Great assistance was afforded by the demonstration of well-marked pathological preparations. Besides the fact that many changes in the membrana tympani observed during life nearly or totally disappeared after death,

the small size of the object rendered it difficult for the beginner to reconcile the state found after death with that observed during life. He had therefore had made a series of fifteen enlarged preparations in wax, showing perforations, calcareous deposits, cicatrices, adhesions, granular myringitis, the formation of vesicles, excessive vaulting inwards, etc.

Abnormal Membranes in the Larynx.—Dr. M. Bresgen exhibited two larynges, showing apparently congenital membranous bands running an abnormal course.

February 4. *Large Nasal Polypi*.—Dr. W. Roth showed three large polypi, which he had removed from the middle meatus of the nose of a man aged thirty-five.

Pemphigus.—Dr. J. Neumann described a case of pemphigus, with microscopical demonstrations. During the occurrence of slight symptoms of angina, a nodulated uneven excoriated spot as large as a thaler appeared in the skin of the axilla; it grew rapidly, and for some time presented the appearance of the confluent form of syphilis cutanea vagitans (*frambœsia syphilitica*). Later on, bladders varying in size from a pea to a hazel-nut appeared and burst, their bases assuming the appearance of broad condylomata. After the disease had lasted six weeks, it first assumed the form of pemphigus vulgaris. The contents of the vesicles was at first serous and gummy-looking; at a later period, the new vesicles contained a small amount of water, which quickly underwent decomposition. The patient died. A similar case, ending in recovery, had been described by Hebra, in which, after the bursting of the vesicles, whitish-yellow convex masses formed in their bases, being closely adherent to the cutis; they were recognised as 'croupous' exudation. In the author's case similar protuberances were present, but they did not appear until the contents of the vesicles had been some time discharged. They did not consist of croupous exudation, but of newly formed tissue, containing new papillæ and large vascular loops, with exudation-cells and pigment. These new growths were formed within a short time in parts, such as the axilla and abdominal wall, where no papillæ existed in the normal state. The sweat-glands were distended, partly by dead cells, partly by a homogeneous membraniform exudation.

Hegar's Injection Apparatus.—Dr. Mader described Hegar's apparatus, and spoke of its utility. It consisted merely of a terminal piece and a glass funnel, connected by an India-rubber tube. The resistance to the introduction of water into the rectum was very small; a column of fourteen centimètres (five and a-half inches) in the tube was sufficient to keep up a constant stream. If the patient were placed on the knees and elbows, the resistance became *nil*. Mosler had found that fluid passed ten feet beyond the ileo-cæcal valve in a girl, aged fourteen, without producing the least distension. This was of importance in regard to internal incarceration, inasmuch as success might be expected even when the obstruction was high up. As regarded quantity, Mosler had injected five litres of fluid, but Dr. Mader used only three. When this quantity was reached, two patients experienced fulness and distension. The indications for the use of the apparatus were described as being the following. 1. The administration of enemata. The apparatus does not produce pain or danger, and is suited for children as well as for personal use. 2. The treatment of diseases of the rectum by the injection of

medicines in solution, such as injection of a one per cent. solution of tannin in chronic dysentery. 3. The completion of the treatment of tænia by the removal of the head. 4. In internal incarceration; even though the only result be to determine more accurately the seat of obstruction. 5. In the diagnosis of abdominal tumours. 6. In affections of the urinary bladder (in which a double-current catheter is also useful), and in pyo-pneumothorax. 8. As a substitute for the stomach-pump in the mechanical treatment of affections of the stomach.

MEDICAL SOCIETY OF BERLIN.

January 5, 1876. *Transposition of the Viscera.*—Dr. Guttman demonstrated a case of transposition of the viscera. He said that more than one hundred cases of this anomaly had been recorded. Transposition was more frequent in males than in females, in the proportion of about two and a-half to fifteen. In 90 per cent. of the cases it affected both thoracic and abdominal viscera; in 10 per cent. the abdominal viscera alone. In about 75 per cent. of the cases of thoracic and abdominal transposition, it was complete; in 25 per cent. it was more or less incomplete. Transposition of the abdominal viscera alone was more frequently incomplete than complete. In complete transposition, not only was there inversion of all the asymmetrical organs and their appendages (the uterus and bladder preserved their position in the middle line), but also of the symmetrical organs, vessels, nerves, etc.; for instance, the right lung had two lobes, the left three; the left kidney lay lower than the right, the right testis lower than the left, etc. The transposition of the thoracic and abdominal organs was not always regular; anomalies of formation, defective development, etc., occurred in various organs, especially in the heart (in 10 per cent.); in some cases there were malformations which could be recognised by external examination. Life was not shortened by transposition of the viscera; in more than half of the cases, the ages of the individuals varied between twenty and eighty-four years.

As regarded diagnosis, the position of the heart, liver, spleen, and stomach could be recognised by percussion; also, with some probability, that of the rectum and colon, especially when the resonance in the left iliac region was constantly louder and more tympanic than in the right. Further, the position of the stomach in the right hypochondrium, and of the œsophagus to the right of the trachea, could be recognised by auscultation better than by percussion; in swallowing fluids, the splashing sounds in the stomach and trachea could be heard in these situations. Transposition of the lungs might be recognised if the pectoral fremitus and the bronchial expiratory murmur, audible over the bifurcation of the trachea, were heard more loudly on the left side than on the right. As regarded the question whether the slight convexity of the spine towards the right depended on right-handedness or on the course of the aorta on the left of the vertical column, the latter supposition appeared the more probable. Notwithstanding that right-handedness was met with in eleven cases out of thirteen, in ten out of fifteen the convexity was to the left, the aorta lying along the right of the spine.

Dr. Guttman showed a man, aged forty-four, the subject of complete transposition. There was no family history of malformation; all his children were

normally formed. He was moderately strong, and had been in good health up to three years previously, since which time he had complained of cough and occasional shortness of breath. The heart's impulse, feeble and diffused, was felt in the fifth and sixth right intercostal space, two centimetres to the inner side of the nipple. The cardiac dulness began at the fourth right rib, reached downwards to the sixth, and as far as the right edge of the sternum. The sounds of the heart were perfectly clear; the cardiac pulsations were eighty in the minute. From the sixth right rib downwards a rather high tympanic resonance was heard, corresponding to the stomach; when water was swallowed, a splashing sound was heard in this situation. On the right side, splenic dulness commenced at the ninth rib and extended downwards to the eleventh. On the left side, pulmonary resonance was found as far as the seventh rib; liver-dulness began at the seventh rib in the nipple line, at the sixth intercostal space in the parasternal line, and at the eighth in the axillary line. The liver could be felt on deep inspiration in the left hypochondrium. The differences of resonance in the iliac regions were too inconstant to allow the position of the colon and rectum to be determined.

There were slight pulmonary emphysema and catarrh; hence, the heart being more covered, the cardiac dulness was somewhat reduced; the upper limit of the liver-dulness also lay more deep, and the area of splenic dulness was reduced. The pectoral fremitus was stronger on the left side than on the right; and in the left supraspinous region, close to the spine, the bronchial breathing was audible during expiration, but not in the right; this indicated transposition of the lungs. The dorsal spine was nearly straight as far as the seventh dorsal vertebra, and was then convex to the left. The right testis was lower than the left; the man had varicocele on the right and inguinal hernia on the left. He was right-handed; the two halves of the body were equally developed; no difference between the arms or between the thighs could be found by measurement.

January 12. In commenting on Dr. Guttman's case, Dr. Lewin called attention to a fact not hitherto observed in cases of transposition; namely, the ending of the right internal spermatic vein in the right venal vein. In the normal state, the right internal spermatic vein opens directly into the inferior vena cava; the left into the renal vein of that side, at a right angle. The abnormal disposition to which he referred probably existed in the present case, there being varicocele on the right side.—Dr. Henoch believed that cases of transposition of the viscera were much more frequent than was generally supposed, but that they were not recognised during life. He had found it, in a complete form, in a child a year and a-half old, who was brought into the Charité Hospital in a state of collapse and died.—Dr. Tiburtius had found transposition in a complete form twice in 20,000 soldiers.

The Inorganic Constituents of the Urine.—Dr. Zuelzer said that, though the mineral constituents of the urine had not yet received sufficient attention, there was no doubt that they played an important part in the system. Liebig had shown that the inorganic matters remaining after incineration of the same organs of different animals showed a constant relation to one another. Further, it had been shown that there was a relation between both the combustible and incombustible parts of individual organs. It had been proved by the analyses of

Forster and others, that the relations between the nitrogen and phosphoric acid remained alike. As the change of substance proceeded equally in all constituents of the body, the existence of great regularity in the composition of organs (and of food) would lead one to expect a constant relation in the elementary products. A disturbance in this respect indicated some alteration in the tissue-change; and a knowledge of the mineral constituents of the urine afforded a view of the process of tissue-change more complete than that derived from examination of the nitrogenous substances alone. As an example, Dr. Zuelzer described the results of a long series of researches on phosphoric acid. If phosphoric acid were exclusively derived from the albuminates, the relation between the phosphates and the nitrogenised bodies in the urine must be constant. Indeed, Pettenkofer and Voit, with others, alleged that the excretion of phosphoric acid ran parallel with that of nitrogen. This, however, was contested, and the question was not yet settled. A stable relation between the phosphoric acid and nitrogen in the urine would eventually show that, *cæteris paribus*, both these substances were derived from combinations which always had similar percentages of them. In the contrary case, it would have to be assumed that substances were decomposed within the organism, so that the relation of phosphoric acid and nitrogen to each other varied. On feeding dogs with meat, Dr. Zuelzer found that, in twenty-four hours, with 100 parts of nitrogen, twelve or fourteen parts of phosphoric acid were eliminated. When the animals were fed with potatoes, bread, etc., or with brain-substance, the relative amount of the phosphates was increased. During fasting, also, there was an increase in the amount of phosphoric acid relatively to the nitrogen. In healthy men, the relative quantity of phosphoric acid varied only slightly. It generally oscillated immediately after meals; but at other times of the day was constant, though dissimilar. There was a relatively smaller excretion of phosphoric acid in the forenoon than at night. The excretion was relatively greatest in earliest childhood, relatively least in powerful middle age. In febrile processes, these relations underwent a characteristic change. During the stage of high pyrexia, there was a remarkable increased elimination of nitrogen, with a relatively decreased elimination of phosphoric acid. In deferrescence large quantities of both were discharged, and in convalescence, especially at the beginning, the quantity of phosphoric acid predominated. In cholera, the urine first passed after an attack was rich in phosphates, the quantity of which was constantly diminished as convalescence advanced. In acute atrophy of the liver, and in Addison's disease, the amount of phosphoric acid was reduced throughout the whole course of the disease; in the former, according to Frerichs, it entirely disappeared. The relative quantity of phosphoric acid appeared to be increased after the use of narcotic doses of morphia, chloral, chloroform, etc., and to be diminished after the use of alcohol, strychnia, etc.; it was also increased (relatively) by warm baths, bodily exercise, and deficient supply of oxygen, and was reduced by cold baths, etc. Dr. Zuelzer arrived at the following conclusions. 1. In similar external conditions, the relation of phosphoric acid remains constant. 2. It varies when different influences act on the body; during excitement the excretion of phosphoric acid is relatively diminished, while in states of depression it is increased. As it was principally nervous influences

which brought about the most essential changes in the relative value of the phosphoric acid, it might be inferred that these were to be preferably regarded as the expression of the tissue-change in the nerve-substance. This view was supported by the evidence afforded in Weiske's experiments, that, even when the food was deficient in phosphoric acid and lime, the formation of the bones was not impeded; while in analogous circumstances, according to Forster, the nutrition of the brain was almost the only change produced. On the other hand, Dr. Zuelzer remarked, the relative amount of phosphoric acid in the urine was greatly increased after injuries of the brain.

ACADEMY OF MEDICINE IN PARIS.

February 29. *Ocular Myotomy*.—M. J. Guérin read a memoir on ocular myotomy by the subconjunctival method, of which the conclusions were as follows. The principles of the operation are, 1. To destroy all the elements and to destroy only the material etiological elements of the deformity; 2. To try to obtain the end-to-end junction of the divided muscles, without adhesion with the globe of the eye; 3. To maintain the divided extremities at such a degree of separation that the intermediate distance shall neither be too short nor too long; 4. To be as careful as possible with the anterior insertion of the fascia into the sclerotic; 5. To avoid firm and extensive adhesions of the fascia with the sclerotic, so that its layers may continue to glide more or less freely over the eyeball. The means of fulfilling these principles are the following.—*a*. The subconjunctival-method, just as well as the other methods of ocular myotomy, affords all the other means of attacking and destroying the etiological elements of the deformity; the dissection-method always in this respect fulfilling the most extended indications, to which the puncture-method would not respond. But the subconjunctival method alone allows of reaching these elements only, the puncture-method having the capability of limiting at will or even entirely avoiding the division of the membranes surrounding the muscles. *b*. It obtains the union of the two ends of the muscle, without adhesion with the sclerotic, preserving as intact as possible the membranous sheath, which acts as a conducting tube for the plastic matter. This condition is perfectly fulfilled by the puncture-method, in which the sheath is only divided diagonally, and may even be left completely intact. It is just the same with the dissection-method, in which the superficial layer only is raised to trace the muscle to its origin. *c*. By allowing the division of everything necessary, and nothing but what is necessary, the two stages of the method allow better than any other the proportioning of the separation of the muscular extremities to the degree of retraction measured by the degree of deviation, and also by the other characteristics of the deformity. Thus it assures a proper length to the newly formed intermediate matter, and this result is obtained by the use of mechanical movements of the eye by means of orthopædic spectacles. *d*. The anterior insertion of the fascia to the sclerotic remains nearly intact in the puncture process, which only inflicts a simple puncture, and in the dissection-method which only raises the superficial layer while preserving the attachments of the deep layer, and when, exceptionally, the retraction of the fascia necessitates to a certain extent the detachment of the anterior insertion of the two layers as the

extent of the dissection is always made in proportion to that of the retraction, so far from destroying, we only bring back the methods of union belonging to the globe to their normal condition. *e.* Finally, the puncture-method, by leaving the cell and the muscular sheath almost completely intact, allows of the play of the fascia over the globe of the eye after cicatrisation. The results were described as being as follows. Out of 192 operations, after one operation only, complete rectification occurred in 156, or 5 out of 6; deviation in the direction of the strabismus operated on in 30, or 1 in $3\frac{1}{2}$; deviation in the opposite direction in 6, or 1 in 32; re-establishment of movement as far as the contact of the cornea and the palpebral angle, in 176, or 11 out of 12; reduction of motion in the direction of strabismus operated upon in 10, or 1 out of 19; reduction in the opposite direction in 27, or 1 out of 7; reduction in both directions in 6, or one out of 32. After a second operation, complete rectification was produced in 175, or 11 out of 12; re-establishment of motion as far as the contact of the cornea and the palpebral angle in 153, or in 10 out of 12.

But beyond the anatomical restoration there is physiological restoration. And the material result of the operation on the regularity of the form of the eye and its movements, as every separate fact has borne testimony, exercises the greatest influence on the re-establishment of the visual functions. The changes of these functions, which are the necessary and direct effect of the changes of relation between the humours of the eye, whether permanent, in consequence of permanent deformities of the eye-ball, or temporary in consequence of the want of harmony of these movements and of the abnormal pressures thence resulting, these changes, according to M. Guérin, have diminished, and even, in some cases, have disappeared entirely with the disappearance of the causes which have produced and kept them up. The evil done by function has been corrected by normal function; in both these cases, function has destroyed and restored the organ. It is by this claim that the perfection of the operative system has become the key and the condition of the functional restoration consecutive on organic restoration, both of them in direct correlation with the operative method used.

March 14. *Lymphorrhagia*.—M. A. Desprès read a memoir on lymphorrhagia, consecutive on suppurative adenitis, and suppurative lymphangitis. The conclusions of this paper were as follows. 1. Suppurative adenitis and suppurative lymphangitis are generally followed, during the twenty days which follow the opening of the abscess, by a flow of lymph which delays the cicatrisation of the incision. 2. The escape of the lymph may acquire abnormal proportions, and constitute a lymphorrhagia. 3. Lymphorrhagia consecutive on suppurative adenitis is more considerable than lymphorrhagia consecutive on suppurative lymphangitis. 4. A more or less copious lymphorrhagia is the real cause of fistulæ consecutive on suppurative adenitis in healthy or scrofulous subjects. 5. Compression, whenever applicable, stops lymphorrhagia in a few days; cauterisations finally stop lymphorrhagia when it has not been found practicable to employ compression. 6. Lymphorrhagia and the flow of lymph, after angioleucitis and suppurating adenitis, are the rigorous demonstration of the primitive lesion of the lymphatic glands and vessels in suppurative adenitis and angioleucitis. 7. Finally, it results from the preceding conclusions,

that compression made during several days on suppurative adenitis and angioleucitis is the best means of preventing the formation of lymphatic fistulæ.

March 22. *The Ophthalmoscope in Injuries of the Brain*.—M. Giraud-Teulon read a report on the memoir read to the Academy by M. Panas, on the circulatory disturbances visible by the ophthalmoscope in injuries of the brain. He summed up in the following terms the discussion originated by him on this subject. In one of M. Panas's cases, notwithstanding the presence of an extensive fracture of the base of the skull, and of compression of the brain which rapidly became mortal, the phenomena of the papillary stasis were wanting at the death of the patient, which took place on the third day. The only fact recorded was the turgescence of the retinal veins, which is apt to be produced by a simple effusion confined to the interior of the orbit. The differential diagnosis between contusion and cerebral commotion cannot therefore in this case be derived from ophthalmoscopic observation only. It is likewise seen, in this case, that the papillary stasis is quite distinct from the cerebral lesion itself; it is a phenomenon of an exclusively physical order; a fact which may be termed manometric. We are therefore able, adds M. Giraud-Teulon, to commend M. Panas and to agree with him when he says, 'Papillary stasis cannot be considered as being connected with one variety of lesion rather than with another, and it is not allowable to judge the gravity of the lesion by it. All that can be affirmed in the present state of our knowledge is, that papillary stasis indicates the presence of a liquid effused into the meninges.' This conclusion from surgical observations is the same that is furnished by medical researches and already stated in the following terms. 'Swelling of the optic nerve by the venous stasis may accompany all the cerebral diseases which increase intracranial pressure, dropsy, tumours, etc.'

Localisation of the cerebral disease by the simple ophthalmoscopic image (without other symptoms) is therefore almost always impossible. According to what has already been said, we may sometimes draw from it conclusions as to the nature of the disease; but not always. The only case in which we may be certain as to the nature of the cerebral disease, is when we find tubercles in the choroid. Then we are right in diagnosing, from the ophthalmoscopic examination only, a tuberculous meningitis. By adding the observations of M. Panas to the acquisitions already made by the comparative medical anatomo-pathology of the brain and eye, the possession of a positive law of pathology is assured, and the first which may be henceforth founded in this matter. Thus we see acquired to science the existence and the function of lymphatic canalisation, which connect together, in pathology as in anatomy, the cranial and ocular cavities, the mechanism which originates false neuritis or papillary stasis, and defines the differences which separate it from true or inflammatory stasis.

ACADEMY OF SCIENCES IN PARIS.

January 31. *Ferment of Urea*.—A note was read by M. Musculus on the ferment of urea. In a former communication the author had described a reacting paper by which urea might be recognised, even in a very diluted solution. He obtained it by filtering urine which had become ammoniacal and

colouring the filter with turmeric, after having washed it. This filter contains a ferment and becomes brown on exposure to the air, after having been steeped in a solution of urea, by the decomposition of this body into carbonate of ammonia. This ferment is only found in ammoniacal urines, and resembles in its characteristics diastase and pancreatic ferment; it is not modified by alcohol, ether, creasote, nor even by carbolic acid. On the contrary, its action is impeded by acids and alkalis.

February 14. *The Movements of the Heart.*—M. Marey sent a note on the movements produced by the heart when it is submitted to artificial excitation. These movements vary according to the phase in which the cardiac revolution is at the moment of the excitation. The systole induced is the stronger, according as it comes on longer after the preceding spontaneous systole. Likewise after each induced systole a compensating rest is observed, re-establishing the rhythm of the heart, changed for an instant. This rest confirms the law which M. Marey believes he has established; that is to say, that the action of the heart has a tendency to remain constant.

Coagulation of the Blood.—MM. Mathieu and Urbain forwarded a paper in reply to M. Armand Gautier on the subject of the function of carbonic acid in the coagulation of blood. They declared that the desiccation of plasma *in vacuo* does not suffice to deprive it of its carbonic acid; in the same way as bicarbonates resist a temperature of 212° Fahr. M. Gauthier, also, in order to demonstrate that a current of carbonic acid does not coagulate the blood, made his experiments at 46.4° Fahr., which is too low to allow the coagulation of the blood.

Bite of the Rattlesnake.—M. Sacc transmitted to the Academy some documents collected by him in Texas, on the treatment employed against the bite of the rattlesnake, and on the retention of muscular irritability in the turtle after death. The treatment of rattlesnake-bite consists in applying over the wound an ointment, consisting of pounded onions and salt. With regard to the muscular irritability of turtles, the contact of a plate of copper brings on contractions, and an hour afterwards the contact of powdered acetate of soda still produces jerks.

REVIEWS.

The Natural History and Relations of Pneumonia.
A Clinical Study. By OCTAVIUS STURGES, M.D.,
F.R.C.P., Physician to the Westminster Hospital.
pp. 330. Smith, Elder, and Co. 1876.

We can cordially recommend this book to our readers, as carefully and well written by an author who has devoted much time and thought to his subject. The work is well arranged. The natural history of the disease, its morbid anatomy and admissible varieties, its etiology and distinction from other lung-consolidations, are first treated of. A chapter is next devoted to a consideration of its pathology, associations, and likeness to other diseases; and the three final chapters are concerned with its relation to phthisis and to tuberculosis, and to the treatment of the disease in past and present times. We must not omit to add that in a series of appendices will be found a very rich collection of facts, with valuable analyses and statistics, upon which are based the teachings embodied in the text.

Dr. Sturges considers that there is but one disease to which the term pneumonia is rightly applicable, the acute exudative pneumonia of other writers, a general disease, of which the lung-inflammation is but the local expression, as the intestinal ulcers are the lesion of enteric fever. He would place pneumonia amongst such diseases as quinsy, rheumatic fever, erysipelas, which are not acute specific fevers, yet in which the local phenomena are probably due to the working of some specific poison. In its being a general affection attended with an increasing hyperinosis of the blood and having a special tendency for some particular seat of inflammation, the author discerns in pneumonia a peculiar analogy with rheumatic fever; the lung and pleura being the selected points of attack in the one and the pericardium in the other disease. In endeavouring to establish this analogy he lays, we venture to think, too much emphasis upon pericarditis as being the local lesion of acute rheumatism, whereas, in fact, it is a mere complication not presenting itself in more than a quarter of the cases. It would be difficult, on the other hand, to diagnosticate pneumonia in the absence of its special lesion.

While in its salient features pneumonia stands widely apart from those insidious lung-consolidations which are apt to complicate and to hasten the termination of many chronic and fatal maladies, yet in minute anatomy the respective consolidations do not, the author thinks, greatly differ, the products of alveolar catarrh being in all cases more or less mingled with those more strictly exudative. But from phthisis, pneumonia from the first differs in the absence of any thickening or destruction of the alveolar walls. With reference to the morbid anatomy of the several periods of the disease, the author appears to us to speak too exclusively of the grey stage as a stage towards purulent destruction of the lung. He does not refer to the degeneration of the exuded products as a step towards recovery. The pathology of convalescence has in most diseases yet to be written; but respecting pneumonia this much at least is known, that the grey stage is common to both favourable and to unfavourable cases, but that in the one it proceeds to purulent infiltration, in the other its products are simply absorbed or expectorated. The woodcut showing the cell-proliferation within the alveolar wall no doubt indicates the true nature of the destructive processes. Many patients die in the grey stage of pneumonia, however, whilst the lung is undergoing normal retrogressive changes. It might be well in a future edition more definitely to point out the pathology of such retrogression.

The chapter on the etiology of pneumonia, although brief, yet contains the interesting results of much careful labour. It is here shown how a low temperature and an increased rainfall influence rather the mortality from bronchitis than from pneumonia; nor do damp and marshy districts specially favour the latter disease. Cold winds and elevated regions entailing brisk currents of cold dry air are favourable to the prevalence of pneumonia.

Dr. Sturges' ingenious explanation of minute crepitation is well-known, and is fully discussed in the first appendix; we need not now refer to it further. In discussing the treatment of the disease he refers to abundant statistics in appendix G; but he well points out the innumerable fallacies connected with such a method of gauging the efficacy of treatment in such a disease as pneumonia. And in truth, were

one satisfied with percentages, one would only rest amazed at the large proportion of individuals who have in the years that are past survived alike the disease and its remedies with which they were simultaneously attacked. Such figures, however, we must remember, inform us only as to the list of killed; they take no account of the wounded, and one may rightly conclude that but a small diminution in the mortality from this, as from any other disease, signifies a large increase in the genuine recoveries. Hence the results of the modern treatment of pneumonia are, we may hope, more encouraging than directly appears from statistics.

Dr. Sturges wisely counsels the alleviation of pain by such local measures as hot fomentations, and the application of a few leeches, and prefers the subsequent administration of a moderate opiate to secure rest, rather than endeavouring to obtain a troubled repose by narcotics alone. In certain cases, however, he would abstract blood more freely. He is inclined to regard the pulmonary hepatisation in pneumonia in the light of a hæmorrhage, as an escape into the lung from the surcharged blood of fibrinous material, it may be to the extent of three pounds. When the dyspnœa continues urgent after exudation has been completed, and provided there be no prostration, he would counsel venesection to ten or twelve ounces. And if, after an interval of marked relief from this practice, the dyspnœal symptoms should return, he would advocate a repetition of the bleeding. Various other points of treatment are discussed with equal judiciousness. The work is most commendable in its thoroughness, and will well repay a careful perusal.

Reminiscences of Obstetrical Practice. By H. SPÖNDLY, M.D., Professor in the Medical Faculty of the University of Zürich. Zürich: 1875.

Dr. Spöndly divides his experience under four heads. Firstly he describes what he calls an 'obstetric night,' wherein he was called to five labours, four being complicated, one a *post partum* hæmorrhage, and three requiring forceps; the sixth, which was also a complication, he was too exhausted to attend.

Secondly, he treats of retained placenta after abortion, and advocates most strongly their early removal. A succinct history of thirty cases is given. In one only was there a fatal result, in which labour had been induced for a dead fetus; the mother being much distressed with severe rigors. The fetus was putrid, as also the placenta, on its removal on the third day. Death occurred from metrophlebitis in the fourth week. Twice partial removal only was possible, but the hæmorrhage at once ceased. In one case the placenta was delivered in the tenth week from excessive metrorrhagia.

The result of his practice has made him come to the following conclusions.

1. One cannot depend upon the placenta being always spontaneously expelled with the fetus; and adhesions are unfrequent.

2. A retarded delivery of the placenta is always accompanied with considerable danger, especially from repeated floodings, which in the most favourable circumstances delay convalescence.

3. It is strongly to be recommended to remove the placenta with the fingers in the early stages, when the cervix is dilated sufficiently to admit at least one finger. Instruments are not necessary.

4. Injections of carbolic acid diluted in warm water should be used to remove portions of placenta which may be left *in utero*. These retained portions are much more frequent in ordinary abortions than with this operation.

5. Care should be taken to use no force to enter the uterus when it is closed without previous dilatation.

6. Midwives should be instructed to send for medical help whenever the ovum is incompletely expelled, as then the uterus, as a rule, would be found permeable.

Multiple births form the subject of the third division. Twenty-nine cases came under his immediate observation, of which one was triplets. Of these twenty-nine cases eleven were primiparæ, five in the second pregnancy, six in the third, two in the fourth, one in the fifth, one in the sixth, two in the ninth, and one in the tenth. Their relative ages were fourteen between twenty and thirty, fourteen between thirty-one and forty, and one over forty years. Three primiparæ were thirty-three, thirty-five, and thirty-eight years respectively. Two had already had twins. In one case the father was a twin, in another the mother. Five were prematurely confined (three to four weeks). There were seven maternal deaths: of these two had placenta præviæ; one, with triplets, had tuberculosis; and one puerperal convulsions, with contracted pelvis and tuberculosis. As to the position of the twins, eleven times there were two head presentations, six times head and breech, six times head and transverse, three times two breech-presentations, and three times breech with transverse presentation. As regards sex, ten times both were boys, eleven times girls, and eight times mixed. In twenty cases there were two placenta, frequently attached to each other; in nine cases one placenta. When the children are of the same sex, they spring no more frequently from one ovum than from two. The placenta was adherent four times. In fifteen cases the second birth occurred within the hour, and in nine between two and twenty-four hours.

Turning was performed by Dr. Spöndly 119 times, besides five times by external manipulation. In the latter case all the children were born alive. Of these 119 cases eighty-five were for shoulder, and two for hip presentations, fourteen for placenta præviæ, eight for transverse presentation with second child in twins, six for high oblique presentation of the head with other complications, and four for prolapse of the funis.

The mortality of the children was very great, viz. 63.9 per cent. The three great factors in its production were, the period of escape of the liquor amnii, the capacity of the pelvis, and the extraction.

The influence which the escape of the waters had upon the life of the child is well exemplified in the shoulder presentation. Out of eighty-five cases with thirty-one living children, with the exception of three the membranes had ruptured either just before or during the operation; whereas with the forty-five still-born children, twelve times the waters had broken from one to nine days before, nineteen at least two hours, and three only during turning.

The effect of contraction of the pelvis (that is, from 3 1/2" to 3") was that out of thirty-eight cases twenty-nine children were delivered dead and nine living; out of the twenty-nine still-born three may be deducted, as being complicated with other conditions. Out of these thirty-eight cases the waters had escaped in twenty-four long before the operation. Dr. Spöndly

declines to decide which was the most important factor in this result, the early rupture of the membranes or the pelvic contraction.

The influence of extraction in causing the death of the child has been universally accepted; out of seventy-six still-born children forty-eight were dead before turning; out of the remaining twenty-eight, thirteen died during extraction, and fifteen apparently dead soon became so. He considers that extraction takes its place next to the early ruptures of the waters in the causation of death.

The maternal mortality was very great, 13·4 per cent.; six had shoulder presentations, seven placenta prævia (out of fourteen), two twins, and one ovarian tumour.

As to the ages of the women and the number of the pregnancy, between the ages of twenty and thirty there were sixty-four cases; between thirty-one and forty, forty cases; and fifteen between forty-one and fifty. In these three decades, with first pregnancy there were nine cases, seven in the first decade, and two in the second. With the second and third pregnancies there were forty-nine cases, of whom thirty-seven were in the first decade, seven in the second, and five in the third. With the fourth, fifth, and sixth pregnancies forty-three cases, of whom seventeen were in the first class, twenty-one in the second, and five in the third. Over 57 per cent. of the cases were with second, third, and fourth pregnancies.

[The great mortality of the children and of the mothers, especially of the latter, in placenta prævia, is very remarkable, and decidedly out of all proportion to the experience of consulting physicians in England. It is the result of Dr. Spöndly's private and consulting practice; the majority were, however, consultations with professional brethren and midwives.—*Rep.*] W. C. GRIGG, M.D.

The Development of Ova, and the Structure of the Ovary, in Man and other Mammals. By JAMES FOULIS, M.D. (Edin.) Reprinted from the Transactions of the Royal Society of Edinburgh, vol. xxvii. 1875.

After giving a brief history of his subject and an abstract of the views of Pflüger and Waldeyer, Dr. Foulis describes the results of his own observations on the ovaries of calves, kittens, and the human female. The following is a brief summary of these results.

The corpuscles of the germ-epithelium are derived by direct proliferation from the columnar corpuscles investing the median side of the Wolffian body, and which are continuous with the columnar corpuscles lining the pleuro-peritoneal cavity in the embryo in its early stages of development. The stroma of the ovary is derived from the direct outgrowth of the interstitial tissue of the Wolffian body which lies immediately below these columnar corpuscles.

The germ-epithelial corpuscles proliferate by fission. In the human foetal ovary of 7½ months they measure $\frac{1}{2500}$ to $\frac{1}{2000}$ of an inch in their longest diameter, and $\frac{1}{3000}$ of an inch in their shortest. Each corpuscle is a nucleus surrounded by a thin film of clear protoplasm. The nucleus becomes the germinal vesicle of the mature ovum, and every germ-epithelial corpuscle is potentially an ovum. In order to form the ovum the nucleus swells, becomes spherical and nucleated, and around it clear homogeneous protoplasm is produced which forms the yolk.

Germ-epithelial corpuscles can be seen in all stages of development into ova. All the ova are so derived. The germinal vesicle possesses a sharply defined, limiting membrane.

The germ-epithelial corpuscles are gradually embedded in the stroma of the ovary by the vascular connective tissue which forms it growing in between and around them. At first groups are so separated; but eventually each one is separated from its neighbour. New corpuscles are formed on the surface to replace those imbedded, and those imbedded increase by division.

The stroma of the young ovary consists for the most part of fusiform connective-tissue-corpuscles and blood-vessels. The walls of the vessels are formed of these connective-tissue-corpuscles.

The connective-tissue-corpuscles are found in close contact with the yolk of each primordial ovum as it becomes separated from its fellows. In all parts of the ovary the nuclei of the connective-tissue-corpuscles are found dividing; sometimes they are seen swollen out into round bodies containing three or four nuclei.

The meshes of connective tissue which grow in between and separate the ova in the egg-clusters as they surround a single ovum form the Graafian follicles. As a rule each Graafian follicle only contains one ovum. The wall of the Graafian follicle with its connective-tissue-corpuscles is in close contact with the yolk, and the latter indent it. The membrana granulosa is formed by the division of these connective-tissue-corpuscles which lie in contact with the yolk, their nuclei swelling out into little vesicles, and eventually forming a perfect cap-ule round the egg. At first the membrana granulosa or follicular epithelium consists of a single layer of cells, measuring about $\frac{1}{3000}$ of an inch in diameter. The corpuscles of this single layer afterwards proliferate, and many layers are formed. The cells of the membrana granulosa are thus derived from the corpuscles of the connective-tissue-stroma, and not, as Waldeyer states, from the germ-epithelial corpuscles.

The follicular space is formed by the breaking down and probable solution of some of the corpuscles of the thickened follicular epithelium. The discus proligerus consists of the follicular epithelial corpuscles in contact with the zona pellucida of the ovum. The zona pellucida or vitelline membrane is formed by the hardening of the outer part of the yolk or protoplasm of the ovum, and is not, as stated by Reichert, Pflüger, and Waldeyer, a product of the follicular epithelium. At birth, the human ovary contains about 30,000 ova, few of which reach maturity.

In the human ovary at birth, the germinal vesicle measures $\frac{1}{1500}$ to $\frac{1}{1200}$ of an inch. Some contain two or three germinal spots. The tunica albuginea is the thickened stroma growing round the ovary. At the age of two and a-half, all formation of ova from the germ-epithelium has ceased.

Graafian follicles are not formed from tubular structures in the way described by Pflüger, Spiegelberg, and Waldeyer. The appearances of tubular structures are produced by sections through furrows and depressions between irregular prominences on the surface of the foetal ovary. These prominences are produced by the expansion of the egg-clusters under the germ-epithelium. If the walls of these furrows come into contact, egg-clusters may be thus formed, just as by the usual embedding process.

At the age of six years the epithelium on the ovary consists of very small flat hexagonal cells, measuring $\frac{1}{2500}$ to $\frac{1}{3000}$ of an inch. The corpuscles are seen dividing. This layer can be stripped off without difficulty. At the age of twelve there is little change. The epithelium is beautifully seen in old cats; it must be regarded as homologous with the peritoneal epithelium. In these old cats the epithelium on the surface of the ovary consists of small distinct cells, measuring from $\frac{1}{1800}$ to $\frac{1}{2000}$ of an inch, with granular oval nuclei. Dr. Foulis's paper is enriched by five beautiful lithographic plates, each containing many figures, and all copied from drawings made by himself, with the aid of the camera, from his own preparations.

J. KNOWSLEY THORNTON.

A Text-Book of Electricity in Medicine and Surgery, for the Use of Students and Practitioners. By GEORGE VIVIAN POORE, M.D. Lond., M.R.C.P., etc.; Assistant Physician to University College Hospital; Senior Physician to the Royal Infirmary for Children and Women; Fellow of University College; University Scholar in Medicine; Commander of the Dannebrog, etc. Pp. 291. London: Smith, Elder & Co. 1876.

Every now and again one hears a deep growl from some medical Thersites about young fellows writing medical books. The growl generally comes from some middle-aged medico who has never written a book himself. The self-appointed critic, not without some show of reason, urges that what the medical public want is experience. 'What,' he says, 'can these young fellows know about it? Here's a big book from one of them, with more chapters than its writer has years, and almost as many pages as there are days in his life. We want books from our Nestors and Ulysses, not from those beardless and embryonic authors, who only scribble to get the practice about which they profess to write!' Granting that there may be some grains of truth in these remarks, their author would be forced to confess that there are some subjects on which young authors may write better than older ones. Such a subject as the one Dr. Poore has selected is an instance in point. The older school of physicians and surgeons, with few exceptions, agreed to ignore the uses of electricity in medicine. The sum total of all that the student was taught a few years ago at our Medical Schools was something to this effect: 'There are three or four kinds of electricity, and about as many hundred kinds of electric machines. You can kill a man with some of them. You can give shocks with most of them. They are all very pretty playthings, and may certainly prove useful in detecting malingerers, and in curing ideal or hysterical paralysis.'

Thanks to Duchenne of Boulogne, such flippant teaching is scarcely possible any longer at any of our Medical Schools. Drs. Russell Reynolds and Radcliffe, Mr. Netten Radclyffe, Mr. Tibbits, and others, have both by their writings and their practice shown us that, imperfect as our knowledge of electricity is, we are slowly accumulating a mass of facts which will by-and-by prove of the greatest value both to diagnosis and therapeutics. Dr. Poore, if we mistake not, accompanied the Great Eastern steamship on several of her cable-laying trips; and ever since he began to practice as a physician has taken a deep interest in the subject of electricity—has lectured

upon it, and has proved clinically its uses in that class of diseases which he justly calls 'fatigue diseases,' foremost amongst which is 'writer's cramp,' or 'scrivener's paralysis.' These lectures and articles by him, from the *Practitioner* and the *Lancet*, form the basis of the present volume. No one can complain that it is too long. Something less than 300 pages are made to contain almost everything that we really know about the uses of medical electricity. Besides this, the intelligent reader who already knows a little of what we may call the anatomy of galvanic batteries, will be able to discover for himself, by the aid of Dr. Poore's book, what any form of battery he has can effect, and how to make and repair others. We say the reader who already knows a little, designedly—for this is the only weak point of the book, that Dr. Poore trusts a little too much to the reader's previous knowledge. This is a pity, for he writes with great clearness, and his descriptive writing is concise as well as clear. The first edition is sure to sell, and in a second and subsequent editions we trust that Dr. Poore will not take it for granted that his readers have any knowledge at all on the subject. Let him begin at the very beginning, and not assume any prescience on the part of the medical public. We can assure him that there are hundreds of medical readers who do not know one pole or electrode of a battery from the other, and who could not tell how to distinguish them, even to save their lives. This is not their fault, but the fault of their teachers in part, and in part of the general ignorance of the profession on these subjects. A few more illustrations would be needed, and one or two of those used in this edition should be changed. Such an illustration as the one on page 19, for instance, is certainly not clear to the ordinary reader, nor is it elucidated by the text. It is a matter of some interest to those who have tried many forms of battery to find that Dr. Poore confirms M. Tripier's opinion as to the long time during which the Leclanché element batteries [patented by the India-rubber and Telegraph Company (Limited), but sold by Messrs. Weiss for medical purposes] will keep in good working order. He says that, after using one in his lectures, it was put away, without any care, in a cupboard, and found still in working order, after more than nine months of neglect. It is, however, not so useful when the battery is to be used for caustic purposes, the destruction of tumours, such as nævi, &c.

The chapters into which this book is divided are the following: Chapters I., II., and III. are on Principles, Batteries, and the Physiology of Electricity; Chapters IV. and V. are on the Methods of Using it, especially its Diagnostic Uses; the next three chapters are on Electricity as a Stimulant, as an Anodyne and Sedative, and as a Caustic; the last two chapters (IX. and X.) are on the Treatment of Internal Aneurisms, and on Electricity as a Cautery.

To make long extracts would not be fair to the author, as the book is of pocket size. A short extract will, however, convey some idea of the style and of the careful attention to details which distinguishes all that Dr. Poore writes. Speaking of the combined use of artificial respiration with faradisation, in cases of drowning and suspended animation from suffocation, chloroform-accidents, etc., he says (page 143):

'In cases requiring artificial respiration, every moment is of importance, and Sylvester's method of producing it should in all cases be at once resorted

to while the faradising apparatus is being sent for, or is being got ready for use. When the faradising apparatus is ready, faradising may be superadded to Sylvester's method. . . . Lay the patient flat on a table, with the neck thoroughly extended, and the head turned to the left side, so as to prevent the tip of the tongue from falling against the roof of the mouth, and acting as an obstructive valve, and so that the right phrenic nerve may be reached with the rheophore, in the manner indicated, while treating of the application of electricity. One person should carry out Sylvester's method, while another attends to the faradisation. . . . The person who has charge of the faradisation should stand on the right side of the patient, and should press one rheophore well down on the phrenic nerve in the neck, and then when his coadjutor raises the patient's arms to cause inspiration, he should place the second rheophore on the right side of the thorax, on a level with the sixth intercostal space. When the patient's arms are depressed again, he should remove his thoracic rheophore, and make connection when they are again pulled above the head. This should be repeated not more than about twenty times in a minute. If it is effectual a distinct rush of air should be heard whenever the circuit is made. Too strong a current must not be used. A current of such strength as will produce contraction of the muscles of the ball of the thumb should be sufficient.

* 'Some writers advise that the rheophores should be placed upon either side of the neck, on the motor points of the phrenic. We do not recommend this, because of the risk of irritating the pneumogastric nerves too strongly, and so causing the stoppage of the already feebly acting heart. It is not advisable to put either rheophore near the heart. If we can get fresh supplies of oxygen into the lungs, the action of the heart will gradually return to its normal condition, provided the patient be not past recovery.'

The book would be worth purchasing if only for the sections on 'Writer's Cramp,' and is certainly the best manual of medical electricity which has yet appeared.

Vidago, Agua Alcalino-Gaseosa, por el licenciado D. JUSTO DE HARO Y ROMERO. 12mo, pp. 16. Madrid, 1874.

This little brochure, written in Spanish, calls attention to one of the numerous Portuguese thermal waters, of which little is known in England. We wish that it had given a more detailed account of the place.

We learn from the pamphlet and from other sources that Vidago is a new name given to the old Caldas de Chaves, which have been known since the days of the Romans. The baths are situated in the most northerly part of Portugal, not very far from Oporto. They are in a mountainous country, and on the banks of the river Tamega. The neighbourhood is picturesque; there is a good new hotel, with billiards and a garden, and a modern bathing establishment. The waters vary in temperature from 110° to 120°. In mineral constituents they closely resemble those of Vichy, as will be seen by comparing the chief constituents in 10,000 parts of the water of Vidago with that of the Grande Grille at Vichy:

	Grande Grille.	Vidago.
Carbonate of Soda . . .	37.7	46.2
" Potass. . . .	2.7	4.8
" Magnesia. . .	.5	2.5
" Lime . . .	3.1	9.7

Vidago would thus seem to have more soda and more lime than Vichy and less potass and magnesia. It has also a little more iron; but the quantity of that substance and of lithia present are for practical purposes insignificant.

Our small tract gives no hint as to the abundance or otherwise of the waters of Vidago, but if the supply be sufficient, they must be in every way an efficient substitute for Vichy, and all the cases which derive benefit from Vichy should be suitable for treatment at Vidago. The waters contain a good supply of carbonic acid, and are therefore adapted for bottling, and already 300,000 bottles are despatched every year.

We hear little of Portugal now-a-days as a climate for invalids. But though too moist during the winter season—especially in November, December, and January—it offers very considerable advantages during spring. It is in the early part of the year only, before the great summer heats set in, and before the more northern spas are open, that there is much chance of English resorting to the baths of Spain and Portugal. We have recently heard of some English who visit Lisbon in spring and then proceed to the baths of Vidago. Portugal, it may be well to remember, retains its ancient superiority over most parts of Europe in its supply of excellent butcher's meat.

The Sanitary Powers of the Iron Springs of Schwalbach. By RUDOLPH BIRNBAUM, M.D. 8vo. pp. 63, Berlin, 1876.

This balneological essay, as the author very properly styles it, gives a fair and competent account of the operation of the waters of Schwalbach. They are treated of chiefly in reference to the diseases of women and children. Dr. Birnbaum's essay appears to contain no novelties, and not to be founded on extended experience. The author has translated his essay into English in a way on the whole creditable to him, but it is a pity that he did not submit it for revision to some English friend. As no details or local information are given, we presume that the essay is meant chiefly for the medical profession. Schwalbach and its virtues are now pretty well known to English practitioners, and it has long been a favourite resort for English and Russian patients. The waters are excellent of their class, and the situation of Schwalbach is very convenient for English travellers, being close to Wiesbaden and not very far from Frankfort.

J. MACPHERSON, M.D.

RECENT FRENCH BOOKS.

Published by J. B. Baillière and Sons.

La folle du doute (avec délire du toucher), par le docteur Legrand du Saulle. Prix: 2 fr. 50 c.

La vie et ses attributs dans leurs rapports avec la philosophie et la médecine, par E. Bouchut.

La gymnastique raisonnée, moyen infailible de prolonger l'existence et de prévenir les maladies, par Eugène Paz, directeur du grand gymnase médical; 1876. Prix: 5 fr.

Sur le traitement des maladies des femmes au moyen de la méthode du massage, par Gustaf Norström, docteur en médecine de Stockholm. A. Paris, librairie Nilsson, rue de Rivoli, 212.

De l'emploi des préparations arsénicales dans le traitement des maladies du cœur, par le docteur Louis Bouyer, de Saint-Pierre de Fursac (Creuse).

Leçons cliniques sur les maladies des femmes, par le docteur T. Gaillard. Prix: 12 fr.

Published by V. A. Delahaye & Co.

- Clinique médicale, par le docteur Noël Gueneau de Mussy, 2 vol. in-8. Prix : 24 fr.
- Des névroses menstruelles ou la menstruation dans ses rapports avec les maladies nerveuses et mentales, par le docteur Berthier. 1 vol. in-8. Prix : 5 fr.
- Leçons sur les maladies du système nerveux, faites à la Salpêtrière, par le docteur Charcot, recueillies et publiées par le docteur Bourneville, 2e édition revue et augmentée, tom 1er 1 vol. in-8, avec 27 figures dans le texte, 9 planches en chromolithographie et une eau forte; le vol. cartonné. Prix : 13 fr. Tome 2e, 1er fascicule : Anomalies de l'ataxie locomotrice; 2e fascicule : De la compression lente de la moelle épinière. In-8, avec 2 planches, prix de chaque fascicule. 2 fr. 3e fascicule, Des amyotrophies spinales, in-8. avec fig. et pl. Prix : 4 fr.
- Traité pratique des maladies du cœur, par Friedreich. Ouvrage traduit de l'allemand par les docteurs Lorber et Doyon. 1 v. in-8 cartonné. Prix : 10 fr.
- Leçons sur le strabisme, les paralysies oculaires, le nystagmus, le blépharospasme, etc., professées par F. Panas, chirurgien de l'hôpital Lariboisière, professeur agrégé à la Faculté de médecine de Paris, chargé du cours complémentaire d'ophtalmologie, etc., rédigées et publiées par G. Lorey, interne des hôpitaux; revues par le professeur, 1 v. in-8, avec 10 fig. dans le texte. Prix : 5 fr.
- Traité élémentaire des maladies de la peau, par A. Gailleton, (maladies cutanées et vénériennes). 1 vol. in-8. Prix : 6 fr.
- Clinique médicale des affections du cœur et de l'aorte, observations de médecine traduites de l'anglais par le docteur Barella, etc. (le tome 1er est en vente, le tome II paraîtra prochainement), in-8. Prix : 6 fr.
- Étude clinique de la phthisie galopante, preuves expérimentales de la non-spécificité et de la non-inoculabilité des phthisies, par le docteur Metzquer; ouvrage précédé d'une préface de M. le professeur Feltz, in-8. Prix : 4 fr.
- Des infiniment petits rencontrés chez les cholériques, étiologie, prophylaxie et traitement du choléra, avec planches micrographiques, par le docteur G. Danet. 1 vol. in-8. Prix : 5 fr.
- Histoire de la vaccination. Recherches historiques et critiques sur les divers moyens de prophylaxie thérapeutique employés contre la variole depuis l'origine de celle-ci jusqu'à nos jours, par le docteur E. Monteils, médecin des épidémies. 1 vol. in-8. Prix : 7 fr.

Published by G. Masson.

- Traité des maladies de la peau, comprenant les exanthèmes aigus, par M. le professeur Hébra (de la Faculté de Vienne); traduit par M. le docteur Doyon, médecin inspecteur des Eaux d'Uriage. 2 vol. gr. in-8o compactes. Prix : 25 fr.

MISCELLANY.

THE FORCE OF EXAMPLE.—Following the example of the French capital, the municipal council of Lyons has voted a credit of 5,000 francs for the creation of a night medical service in that city.

DEATH AND BURIAL.—M. Dugate has just founded a quinquennial prize of 2,500 francs to be awarded to the best work on the signs of death and the means of preventing premature burial. The prize will be awarded by the Académie des Sciences for the first time in 1880. The theses will be received at the Secretarial department of the Institute up to June 18, 1880.

THE MEDICAL COLLEGE, CALCUTTA.—Dr. F. N. Macnamara, whose name is connected with the establishment of the Campbell Medical School and Hospital, was, on his recent retirement from the post he held at the Medical College at Calcutta, present by the Graduates and students with an address, expressing their sorrow at the prospect of his departure from India. His name is to be preserved in the College by the foundation of a Chemical Prize.

At a recent meeting of the Sedgwick Memorial Committee at Cambridge, the treasurer announced that the fund amounted to 11,500*l*. This sum is, however, insufficient for the purpose of erecting a Museum worthy as a building to commemorate the late Professor, and it is hoped that additional subscriptions will still be forthcoming. It is intended that the Museum should form part of a group of buildings for Natural Science purposes. The whole question is under the consideration of a Syndicate.

NIGHT MEDICAL SERVICE IN PARIS.—Since January 6, when this service commenced operations, up to March 1, the medical men who proffered their services to the authorities have made 630 visits, which may be classified as follows:—Thirty-five of the cases have paid their fees directly to the medical attendant; 215 fees have been recovered by the authorities; 300 seem to have remained unliquidated. The average of visits made throughout Paris amounts to twelve each night.

The Gazette d'Augsbourg states that a young lady has taken her degrees in medicine, surgery, and obstetrics with honours, at the University of Zürich, after having attended the courses during nine consecutive half-yearly terms. This young doctor, whose name is Mdle. Francesca Tiburtias, a native of the Isle of Rugen, read a lecture on the use of protoxide of nitrogen in operations, and, it is said, acquitted herself brilliantly in her theses. The Dean of the Faculty of Medicine made a little speech to her, in which he did justice to her zeal, capacity, and perfect tact.

THE Medical Association of the Bouches-du-Rhône, which has its head-quarters at Marseilles, has instituted an annual and permanent competition in medical and surgical instruments, either of a novel kind or having undergone improvement. The instruments sent to the competition in the course of the year will become the property of the Association; the inventors whose instruments are selected for reward, will receive either a gold, silver, or bronze medal, or an honourable mention, which will be delivered to them at the general meeting of the Association which takes place annually in the April of each year. The instruments should be sent to the Society's rooms at No. 25, Rue de l'Arbre, Marseilles.

STATISTICS OF MARRIAGES AND BIRTHS IN THE GERMAN EMPIRE IN 1873.—From the official report we notice that there were 416,048 marriages, of which 252,567 were in Prussia. There were 1,715,132 births, of which 882,945 were males, and 832,186 females; one, sex undetermined. Of these 67,165 were still-born. Among the infants born alive 1,498,283 were legitimate, and 170,097 illegitimate—a proportion of 1 in 10. There were a

greater number of still-born children among the illegitimate, viz. 59,337, whilst there were only 7,827 among the legitimate, or 13 per cent. The total number of deaths during the year was 1,241,120, of which 647,206 were male, and 593,193 females. The number of births exceeded the deaths by 474,012.

LECTURES ON ZOOLOGY.—A series of lectures upon zoological subjects will be delivered after Easter in the Zoological Society's Gardens, in Regent's Park, on Thursdays, at 5 P.M. The following are the titles, together with the days on which they will be delivered by the respective lecturers:—April 27, Mr. P. L. Sclater, F.R.S., on the Society's Gardens and their Inhabitants; May 4, Professor Flower, F.R.S., Rhinoceroses and Tapirs; May 11, Professor Flower, Horses and Zebras; May 18, Dr. J. Murie, the Manatee; May 25, Professor Garrod, On Birds; June 1, Professor Mivart, On Bats; June 8, Mr. Tegetmeier, On Homing Pigeons; June 15, Professor Garrod, on Reptiles; Mr. J. W. Clark, on the Beaver and its distribution; June 29, Dr. Carpenter, on the Zoological Station at Naples.

AN ITALIAN LOUISE LATEAU.—For some time a rumour has been current in Turin that the city was so fortunate as to possess a miracle-working nun. Every Friday stigmata showed themselves on the forehead, hands, and feet of a holy nun of the hospital of Cottolengo. The authorities, wishing to assure themselves of the reality of the miracle, caused the nun to be examined by the professors Pacchiotti, Rovida, and Giacomini. The medical men made a report that, in the first instance the patient was in a state of great exaltation, which induced her to try to imitate the wounds of the crucified Christ, a *ruse* which, however, had not been successful up to the present time. Secondly, the wounds were produced by sharp instruments, such as needles or pins, and every Friday, when they were nearly healed, they were renewed with the same instruments. The surgeons recommended that the patient should be taken to a hospital to be watched over and cured—a recommendation which has been carried out by the authorities.

ARTIFICIAL DISFIGUREMENT OF THE TEETH AMONG DIFFERENT NATIONS.—At a meeting of the Anthropological Society in Göttingen, Herr von Ihering, after a brief sketch of the principal artificial disfigurements of the teeth in use among different nations, partly for the requirements of their health, partly from hurtful toilet operations, spoke as follows:—The disfigurements of the teeth are substantially of three kinds: 1st. Painting the teeth with red or black colours (Borneo, Birma); 2nd. Knocking out one or more of the incisors in the upper or lower jaw, practised among certain tribes in Australia and Central Africa; 3rd. Mutilation of the form of the tooth whilst preserving the tooth itself. Many tribes from the interior of Africa cut the incisors with the chisel in such a manner that they are sharpened to a point, or so that the point comes in the centre of each incisor, or by apparent prolongation of the edge, on one side or both, they are double-pointed. In the islands of the Malay Archipelago we find filing between teeth (almost always regularly coloured by betel-nut-chewing) in two typical forms: 1st. Removal of the enamel from the entire front surface of the crown of the incisors by horizontal filing and polishing, a kind of mutilation characteristic of the Malays of the East Indian Archipelago; 2nd. Filing in such a manner that the enamel is removed from the front surface with the exception of a three-sided portion, of which one side represents the incisor. The tooth is generally so pointed from the removal of the side part that the remaining enamel of the tooth has a rhombic form. This form is only found upon four islands, Java, Boli, Madura, and Celebes, and has not been observed until quite recently, for Virchow and A. B. Meyer considered the pointed filing of the teeth the characteristic of these islands. The Malay skull, mentioned by Virchow in the Wiesbaden collection, belongs to the

same group. Meyer's idea, that this second form of filing occurred amongst those aborigines fallen into slavery in the Mentavey island, is most improbable, as Von Ithering had met with this example in entirely separated collections, in all of which these four islands were given as their home. It must, therefore, be concluded that these deformities are, or have been, native to these islands, although at present no conjecture has been brought forward to which nation it is peculiar, or whether it is a sign of position in life.

EXTINCT ANIMALS.—A recent lecture at the Royal Institution by Professor Flower, F.R.S., was devoted to an account of discoveries recently made of a vast number of fossil remains of animals which lived in North America during the Tertiary period, especially those found in the eocene strata of Wyoming, Colorado, and New Mexico, only explored since 1869 chiefly by the United States geological survey of the territories under Dr. F. V. Hayden. Of the remains particularly selected for description many are of animals unlike any now existing, or found fossil elsewhere, and many constitute connecting links between living forms now widely separated. There are also many the relations of which have not yet been satisfactorily determined, as the materials have accumulated so rapidly that the united labours of the observers engaged in describing them, especially Professors Leidy, Cope, and Marsh, have not been sufficient as yet to make them fully known to us. Among the most remarkable of these animals are a number of gigantic species, to the first discovered of which the name *Uintatherium* was applied—from the Uintah mountains, near which it was found—in form and size somewhat intermediate between the elephant and the rhinoceros, but differing in some respects from both, and having three pairs of great horn-like projections on the top of the head, and huge trenchant canine tusks. These animals, which were entirely unknown five years ago, have been found in such abundance that the museum of Yale College alone now contains remains of more than a hundred individuals, some of them in excellent preservation. There are also large rhinoceros-like animals with a pair of horns side by side on the nose, and various new kinds of carnivora, rodents, lemurs, etc. Many new forms of the horse and of the camel family have also been found.

DR. ATLEE ON WOMEN AS OBSTETRIC PHYSICIANS.—The following remarks, extracted from Dr. Atlee's address to the Pennsylvania Medical College (*Transactions of the Medical Society of the State of Pennsylvania*, vol. x. part ii.) may not be uninteresting at the present time. Speaking of the Pennsylvania Woman's Medical College, Dr. Atlee says: I allude to the Woman's Medical College. In the days of old physic such a phenomenon as a medically educated woman was unknown, at least in this country. An ignorant fussy old woman, known as 'granny,' officiated on important occasions; and even within the present century was the principal midwife. I venture to assert that many of our most eminent men—physicians, divines, and statesmen—entered this world having their passport *visé* by this important official. It was not until Professors James and Dewees instructed medical practitioners of this country in their proper duties that these uneducated obstetricians began to disappear, and the midwife gradually merged into the more intelligent and more dignified accoucheur. Yet even to this day, in some sections of the country, the services of this old lady are preferred. In the management of the lying-in room, in the most trying position of woman, the substitution of an educated for an ignorant attendant has been a great advance over the past. If uneducated women were the chief practitioners of midwifery in former days, and proved themselves competent in proportion to their knowledge, then we should hail the medically educated woman who will also fulfil her duties according to her acquirements. I know that in the opinion of many, the establishment of a medical college for the education of women is of doubtful expediency, yet I view it as a work in the proper direc-

tion. It is the obvious right of woman to engage in all occupations and professions suited to her ability and her sex, and it affords me much pleasure to announce that after much opposition this society has assumed a correct position on this question. Anatomically and psycho-physiologically the sexes are different; but if we view this difference free from the influence of prejudice, self-interest, and custom, we will find that, so far as the study and practice of medicine are concerned, our organisation has nothing to give it material superiority over that of our sisters. In certain branches of our art, such as the department of operative surgery, particularly in capital operations, we would doubt woman's qualifications; but in the more quiet pursuits of the profession, much can be said in favour of the peculiar qualities of woman over those of man. No doubt there are exceptional women so constituted that they would achieve even brilliant success in surgery. Even among men great surgeons are comparatively few; the majority of medical practitioners being incompetent, from various causes, to practice operative surgery. If, then, we exclude the greater achievements of surgery, which also embrace certain operations in obstetrics, is there anything peculiar in the organisation of woman to interfere with her ability of becoming qualified to fulfil most other duties of the profession? Can she not treat diseases, both surgical and medical, as well as her brother practitioner? Can she not conduct an ordinary case of parturition with the same care and dexterity as the majority of medical men? Can she not with more propriety and acceptance, and with equal success, treat her own sex for that long catalogue of troubles peculiar to them? Can she not minister to the ills and afflictions of infancy and childhood with greater gentleness and equal skill? Even in the minor operations of surgery; in many of the operations on the eye, the ear, the teeth; in the dressing of wounds, and in many other troubles, where delicate and nice manipulation is necessary, educated woman is peculiarly fitted by nature to render aid.

THE MOSAIC CODE AND VITALITY.—Dr. Benjamin W. Richardson, F.R.S., delivered a lecture on March 26 at the Jews' Infant School, Commercial Street, Whitechapel, upon the 'Vitality of the Jews and the Mosaic Sanitary Code.' Dr. Richardson traced through different ages of life the comparative mortality of the Jews and others. In Prussian Germany there was one still-born in 97.75 among Jews, one in 47.29 among Catholics, one in 42.47 among Protestants. These were the statistics of legitimate children; of illegitimate births there were few among the Jews, but a large proportion of the children so born survived. Mayor estimates from the statistics at Fürth that the Jewish children under five die only at the rate of 10 per cent., while the Christian children of the same age die at the rate of 14 per cent. Neufville, making the same observations at Frankfurt, finds that during the first five years of life the deaths of children are as 12.9 among the Jews to 24.1 among the Christians. This tenacity of life is maintained into later periods. At Frankfurt, among the Jews, 54 per cent. reached their fiftieth year; among the Christians 38 per cent. only. Of the Jews 27 per cent. reached the age of seventy, of the Christians 13 per cent. One-fourth of the Jews lived to be twenty-eight and a-quarter years old, while one-fourth of the Christians lived to be six years and eleven months old. Half the Jews at Frankfurt reached fifty-three years and one month, half the Christians succumbed at thirty-six. One-fourth of the Jewish population passed the age of seventy-one; one-fourth of the Christian population exceeded only fifty-nine years and ten months. The Jews marry less frequently, have fewer children, fewer still-born children, and fewer deaths among those they rear, than the rest of the communities, but the vitality among those who live is such that the Jewish population increases in effective strength over others. Dr. Glatter, from the mortality of one thousand persons, gives an average duration of life to Germans of 28.50 years, to Hungarians 23.11, to Croats 22.10, to Jews 30.20 years. Legoyt gave statistics of

suicide in 100,000,000 inhabitants of Prussia, Bavaria, Württemberg, Austria, Hungary, and Transylvania, as follows: Protestants, 616·3; Catholics, 373·9; Jews, 291·4. But in Bavaria the suicides were 135·4 Protestants, 49·1 Catholics, 105·9 Jews. From tables supplied to him by Dr. Asher, Dr. Richardson was able to offer an approximative estimate for London. The deaths mentioned in these tables amounted to 2,563. The interesting fact resulted from them that the mortality among the Jews was highest at the extreme or latest period of life, and lightest at its beginning and meridian. Thus, in the first five years the relation was as 45 for the whole population to 44 for the Jewish; in the meridian of life (between thirty-five and forty-five) it was 3 to 5, and at the extreme of life (from eighty-five years upwards) it was 0·8 to 2, or nearly 1 to 3. The facts were remarkable in the light of the severities amid which the ancestors of living Jews maintained such a tenacity of vital power, locked up in close quarters, debarred from social privileges. Three reasons had been assigned for this high vitality—(1) an innate excess of vital resistance, (2) the observance of the rules of health laid down in the Pentateuch, (3) that the Jews have followed, either under the influence of necessity or from natural prompting, a better life in all that relates to the maintenance of a healthy physical existence. The results were due to all three causes. There was no physiological or anatomical superiority of the Jews over other races. In some respects they were inferior to Saxons and Celts; but they had less hereditary tendency to diseases such as scrofula, consumption, rheumatism. Coming to the second cause, the influence of the Mosaic sanitary code could scarcely be overrated, and its provisions formed a marvellous collection of sanitary rules. The Second Commandment specified the times (the third and fourth generation) required to wipe out the effect of physical degradation. The third, sixth, seventh, eighth, ninth, and tenth, all had reference to the rule of the passions. The fifth takes special care of the aged and infirm, and the fourth, which enjoins a special day of rest, and was seven times repeated, is so important a provision for health that a nation which followed it strictly might, on the purest physiological grounds, expect to realise an extra seventh term of existence. The perfect cleansing of the house, that process which now, as the Passover approached, was about to commence, was one of those great sanitary rules which, carried out by the whole community, would do more to cut off the spread of disease than any sanitary law which a modern Parliament could impose. The cleansing of vessels, the separation of cloths for such cleansing and such ablutions, the baths that are religiously enjoined, the isolation of infectious sick, the purification or destruction of infected houses, were all parts of the scheme. A great advantage was gained by abstaining from the flesh of animals which feed on garbage, and from diseased or decomposed food. In the third category came causes of longevity, which might be called social and moral, as comparative immunity from hard physical labour, the value which persecution had taught the Jews to set upon the family life, their diligent care (it had been called 'extravagant' care) of the young and old. Dr. Richardson also dwelt upon the valuable habit of thought for the morrow which had caused Jews to be accused of parsimony; and on their comparative freedom from intemperance. In conclusion Dr. Richardson exhorted his hearers to continue to obey those wise laws which led to the fulfilment of the prophecy of their own grandest poet, 'When the voice of weeping shall be no more heard nor the noise of crying, when there shall be more an infant of days nor an old man that hath not fulfilled his days; when the child shall die an hundred years old.' Sir Barrow Ellis, who presided on the occasion, confirmed from his long experience in the East the conclusions of Dr. Richardson upon the sanitary excellence of the Mosaic code.

REPORT OF THE CAMBRIDGE STUDIES' SYNDICATE.—The Syndicate appointed in May last year to consider the requirements of the University of Cambridge in different

departments of study have just issued their report. The Board is of opinion that lectures are required in the University on the following subjects among others: Elementary Biology; Systematic Botany:—(1) Elementary and (2) Advanced; Vegetable Morphology and Physiology:—(1) Elementary and (2) Advanced; Zoology:—General. Special: (1) Vertebrates; (2) Molluscs; (3) Insects; (4) other Invertebrates; Comparative Anatomy:—(1) Elementary and (2) Advanced; Embryology, Osteology; Physiology:—(1) Elementary and (2) Advanced; Physiology of the Senses; Physiology of Nutrition; Human Anatomy, including Animal Mechanics, etc.:—(1) Elementary and (2) Advanced; Ethnology. The course on elementary biology might be given by a demonstrator acting under a Professor of Physiology or of Comparative Anatomy. The elementary and advanced courses on systematic botany might be given by one teacher. The elementary and advanced courses on vegetable morphology and physiology might be given by one teacher. A third botanical teacher (for cryptogamic botany) will probably be required at a future time. The general course of zoology requires one teacher. The teaching which is at present required in the special departments of zoology might be given by curators of the Museum, who should also act as demonstrators; but special teachers of each of the four departments will be required eventually. The elementary and advanced courses on comparative anatomy might be undertaken by one teacher. The courses on embryology and osteology might be given by demonstrators; but each subject is important enough to occupy the whole time of a teacher if a suitable one is available. The elementary and advanced courses on physiology require one teacher. The remarks made on embryology and osteology apply also to the subjects of the physiology of the senses and the physiology of nutrition. Elementary and advanced courses on human anatomy might be undertaken by one teacher. The subject of ethnology would be best undertaken by a separate teacher if circumstances should admit. It is desirable that the University should have the opportunity of inviting men who have devoted themselves successfully to the prosecution of special departments of science to give lectures in the University; but the delivery of such lectures must depend rather upon the men being forthcoming than upon any *à priori* consideration of what subjects require elucidation. In Zoology, work-rooms are required for the professor, superintendent of the museum, curators, and demonstrators. In Comparative Anatomy a laboratory is required, including dissecting-rooms, rooms for microscopical work, etc. In Physiology, a laboratory is required, including chemical laboratories, rooms for microscopical work, etc. In Human Anatomy, dissecting-rooms are required, and rooms for microscopical work. Each department will require rooms for research, microscopes and other apparatus, as well as diagrams. In reference to more immediate wants of the biological departments, it may be stated that the present teaching staff consists of the Professors of Anatomy, Botany, and Zoology and Comparative Anatomy, each of whom, except the Professor of Botany, has a demonstrator. The chief teaching of physiology is at present conducted by the Trinity Prælector in Physiology. The additions to the teaching staff most urgently required are (1) a professor or teacher of comparative anatomy; (2) a more definitely recognised teacher of vegetable morphology and physiology; (3) two curators in zoology (molluscs and insects), to act also as demonstrators; (4) two demonstrators of physiology; (5) an additional demonstrator of comparative anatomy; (6) an assistant-curator of the herbarium, to act also as demonstrator of systematic botany; the professor of botany being *ex officio* curator of the herbarium. The appliances most urgently needed are laboratories for chemistry, comparative anatomy, physiology, and vegetable morphology, and work-rooms for the zoological museums. It is desirable that all the teachers in each of the several departments should be grouped in one organisation. The Board considers that

while there is room in the University both for professors and lecturers, appointed directly by the University, and for inter-collegiate lecturers, it is undesirable to have lecturers in natural sciences teaching members of their own colleges exclusively. It appears that physiology, comparative anatomy (as distinguished from zoology), and vegetable morphology and physiology (as distinguished from systematic botany), are so important and so distinct that they should be entrusted to independent professors, but till this can be done the subjects may be undertaken by other lecturers. It seems desirable that the selection of University professors should be entrusted to a body of about seven electors, of whom a majority should be residents in the University; that such electors should be appointed either for life, for a term of years, or by virtue of holding some official post, and that those who are not *ex officio* electors should be nominated by the Board of Studies with which the professorship is connected, and be elected by the Senate. Further, that the selection of other teachers appointed by the University, but not directly subordinate to the professors, should be made by similar bodies of electors in the University, or by the several Boards of Studies, and that demonstrators should be appointed as at present. It seems desirable that in the case of the recognition of individual intercollegiate lecturers by the University, the appointment of such lecturer should receive the confirmation of the several Boards of Studies.

SLEEP AND DREAMING.—In the first of two lectures on this subject given by Dr. Ferrièr, at the London Institution, he commenced by stating the principle that no living thing was capable of continuous or unintermittent activity, it being an inflexible law of nature that a period of work must be succeeded by a quiescent state, during which the organism might repair the loss entailed in its tissues by previous exertion. A muscle was capable of a certain amount of activity, but its energy, after a little while, became exhausted, and the muscle itself powerless and flaccid. That which was true of one muscle was true of the whole body and of its individual organs. Even the heart, the action of which appeared to be incessant, conformed to this universal rule, though its motions were not intermittent, but rhythmical. In fact, there was a distinct period of rest between each pulsation. It was, however, in the case of the brain more than in that of any other organ that we had this principle forced upon our notice. Every act of thought or volition entailed a certain loss or consumption of brain-substance, and the period during which the brain rested for the repair of this loss formed the period of our existence which we termed sleep. Sleep was, however, something more than a time of rest for the brain, as it was the time during which the whole body recouped itself for such waste as had not been made good during the day. A general sketch of the nutritive process in the human body was here appropriately introduced, after which the lecturer enlarged on the well-known physiological fact that a local increase of activity in the system is always accompanied by a corresponding local increase in the circulation. A large proportion—about one-fifth—of the whole of the blood leaving the heart normally flowed directly to the brain. An increase of activity in this organ, as deep thought, increased this flow—a fact proved by direct observation. Now, the approach of sleep was accompanied by a gradual diminution of brain-circulation, and also by a sensible collapse in the substance of the brain. Consequently, during sleep more than the normal quantity of blood was distributed over the remainder of the body, notably over the surface and extremities, which accounted for the extreme liability to take cold during this state; for the warm blood flowing beneath the surface of the skin was very apt to lose a certain portion of its heat by radiation into a cold atmosphere. Any cause tending to promote circulation in the brain, such as worry or anxiety, tended to prevent sleep; and, inversely, any cause tending to diminish the circulation in the brain induced sleep; too sudden a diminution, or entire cessation, producing syncope or death. Warmth

of atmosphere, darkness, and monotony of sound, were all influences inducing sleep by absence of excitation to the brain. The duration of sleep required by nature varied in different individuals, depending inversely upon the rapidity with which the repair of wasted tissues went on in differently constituted organisms. The daily or nightly sleep required by the human subject was probably about eight hours in the case of the average adult. Young children, whose tissues were in a state of rapid growth, slept during the greater part of the twenty-four hours, while old people, on the other hand, whose tissues were in a state of gradual decay, required very little sleep indeed. Dr. Ferrièr concluded the first lecture with some observations on the nature and physiological action of narcotics. In the second lecture, on 'Dreams and Dreaming,' the lecturer said, the brain, though an unity, was a complex unity, and therefore while one portion of it rested others could go on actively. Hence the reflex actions of the brain took place as well, or even better, during sleep than in the waking hours. All ideas were the results of sensory impressions, of which the brain might be termed the organic register, and when we recalled ideas we, in reality, re-excited exactly the same portions of the brain as were originally concerned in taking the impressions. In a converse manner strong ideas might and did occasionally cause absolute sensory impressions—optical illusions, for example, such as occurred to 'spiritualists' and persons labouring under many forms of insanity. Not only might ideal phantasms be thus produced, but pathological changes and even disease might be engendered by a powerful imagination. Dreams were the revival during sleep of impressions registered during waking hours. None of their elements were or could be new; the arrangement alone of the elements might be novel. In short we had in dreams a series of permutations and combinations of facts that had come within our own past or possible experience or knowledge, and therefore to dream of future events was simply impossible. Incoherent dreaming was caused by a kaleidoscopic grouping of impressions. The causes that produced the re-excitation of mental impressions during sleep were various, but might usually be traced either to some disturbing physical or physiological influences on the body, or to the retention of some recent train of waking thought. Thus, indigestion produced the familiar phenomenon of nightmare by transmission to the brain of the sense of oppression on the chest; and concentration of thought on one subject during great part of a day, brought about a morbid condition of the brain-cells, which caused the imagination during sleep to revert to the strongly pre-occupying subject. It was due to this that we occasionally heard of poets, mathematicians, etc., completing during sleep some line, or stanza, or problem on which they had previously unsuccessfully laboured. There could be little doubt that all impressions once made on the brain were permanently retained; it was merely the revival of them that constituted the difficulties of a bad memory. Some persons possessed in an extraordinary degree the power of retaining and combining impressions, the lecturer quoting as an example of this an anecdote from the recent review in the *Daily News* of Mr. Trevelyan's *Life and Letters of Lord Macaulay*. Somnambulism was described as 'active dreaming,' and 'talking in one's sleep' as a mild form of somnambulism. It was an interesting fact that dreams for the most part occurred while the brain was being resuscitated—being frequently caused by the very noise that awakened the dreamer. This led on to a short dissertation on the duration of dreams, which were, as a rule, almost incredibly short. This was explained by the fact that it required but a very brief time to re-excite impressions that were ready formed on the brain, although their formation might have occupied many years. Other topics of interest in connection with the subject were introduced, interspersed with interesting anecdotes, the lecturer on concluding being warmly applauded by a crowded audience.

The London Medical Record.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

FÜRBRINGER AND OTHERS ON THE ANTI-PYRETIC ACTION OF SALICYLIC ACID AND SALICYLATE OF SODA AND THEIR USE IN FEBRILE DISEASES.

During the last and the present years, a number of articles have appeared in the German medical periodicals on the action of salicylic acid as an antipyretic in febrile diseases. By some practitioners also, salicylate of soda has been used.

In an article in no. 18 of the *Centralblatt für die Medicin. Wissenschaften* for 1875, Dr. Paul Fürbringer, of Heidelberg, describes the results of experiments on the antipyretic action of salicylic acid, given internally and by subcutaneous injection. A first series of experiments on the effect of the acid during health was made on ten rabbits and six men; the dose being $1\frac{1}{2}$ grains in the former, and 4 to 8 grains in the latter. No effect was produced on the normal variations of temperature, which had been carefully noted some days before the commencement of the experiment.

A second series of observations had reference to the influence of salicylic acid on septic fever artificially produced in rabbits. In nine cases, there was a distinct lowering of temperature after the administration of salicylic acid. The dose varied from .15 grain to 3 grains. In three cases it was given in starch enema (1 part in 50); in two, it was introduced into the stomach by means of an elastic catheter (1 in 30 of water or decoction of starch); in three it was given by subcutaneous injection (1 in 2 of alcohol or 5 of warm water); and in one, both by subcutaneous injection and by enema. There was no remarkable difference in the effect—a rather rapid fall of temperature, generally from two to six hours after the administration of the dose.

A third series of observations was made on the action of salicylic acid on fever induced by the inunction of croton-oil. No distinct results were obtained.

A fourth series of experiments was made on the effect of salicylic acid on pyæmic fever produced by the subcutaneous injection of healthy pus, diluted with a 0.5 per cent. solution of chloride of sodium. In two observations that were completed, the results were similar to those in the second series.

C. E. Buss, of Basle, contributes an article on the use of salicylic acid as an antipyretic to the *Deutsches Archiv für Klinische Medicin* (Band xv., 5 and 6 Heft). The following are some of the conclusions in which he sums up his results.

1. In its action as an antipyretic in the treatment of wounds, as well as in its action on the human organism, salicylic acid shows a very remarkable agreement with quinine.

2. No other unpleasant consequences are found to

attend the use of salicylic acid than those which follow the administration of quinine.

3. No irritating influence of any importance is exercised on the mucous membrane of the mouth, bladder, and rectum; in the stomach also it is not to be expected. Caustic action, such as is produced by carbolic acid, is entirely absent; and salicylic acid can be administered for a long time without producing gastric catarrh.

4. In healthy individuals, large doses (45 to 60 grains) first produce a stage of congestion, with a feeling of warmth and perspiration over the whole skin, and impaired hearing and vision.

5. When this has ceased, after lasting about a quarter of an hour, it is followed, if the dose be sufficient, in about two hours, by tinnitus aurium, which also disappears in a few hours; the hearing is generally unaffected with this.

6. No influence on the temperature and frequency of the pulse can be observed in healthy persons.

7. Febrile patients, to whom larger doses have to be given, show the above-mentioned symptoms; and, if the dose be increased in a high degree, the difficulty of hearing may last for more than one day.

8. There is a total absence of any other influence, especially narcotic, on central organs, even with large doses.

9. The most remarkable effects of a large dose are reduction of the temperature and of the frequency of the pulse.

10. It may be said that twice as much of salicylic acid as of quinine is required to produce this lowering of temperature; the usual dose of salicylic acid required is from one to two drachms. These doses do not produce collapse or other unpleasant symptoms; vomiting also does not appear to be more frequently produced by a full dose of salicylic acid than by quinine.

11. With the above-mentioned doses, the antipyretic effect of salicylic acid is at least as certain as that of quinine.

12. The greatest antipyretic effect is obtained as a result of cumulative action when two large doses are given in twenty-four hours, one in the morning and the other in the evening.

13. The resistance of the fever varies in different cases and in the individual stages.

14. Salicylic acid can be easily detected in the urine a short time after it has been taken, but mostly after the end of thirty-six hours. Iron salts (especially diluted liquor ferriperchloridi) produce a dark violet colour.

15. Salicylic acid can also, after its administration, be detected in the sweat, saliva, and sputa, by the same reagent.

16. The quantity required being taken into consideration, salicylic acid is five times as cheap as quinine.

17. The treatment by salicylic acid and by cold water may be combined with the best results.

Buss generally gives salicylic acid in doses of 30 grains with 15 grains of sugar; the latter assists the suspension of the acid in water and renders the taste more pleasant. The powder of salicylic acid and sugar may be given in a wafer; or, if the patient object to this, it may be suspended in a little water, the patient, after drinking it, washing his mouth with some pure water, peppermint tea, or peppermint water. The dry powder sticks obstinately to the mucous membrane of the tongue and fauces, and

gives rise to an unpleasant taste, which excites vomiting by reflex action.

At a meeting of the Berlin Medical Society on June 2, 1875, Dr. Senator said that he had given salicylic acid in a number of cases, especially in the hectic of phthisical patients. In about fifty observations, salicylic acid distinctly reduced the temperature in ten, but not so surely as quinine; which, moreover, more frequently failed, especially in hectic fever. In some cases, the result of salicylic acid in reducing the temperature was very remarkable; in others it seemed to have little or no effect. Perhaps this was due to the dose being too small, the medicine being at first given in powder or in emulsion. Of ten cases of quotidian and tertian intermittent fever, four were cured after one or two doses; in the other five cases, the results were not known, as the patients did not return to the hospital. The dose used for adults was eleven to eighteen grains. At first it was given in powder with sugar; afterwards in solution in water and glycerine, warmed before taking each dose. No troublesome results were observed to follow the use of the salicylic acid. It was readily detected in the urine by testing with perchloride of iron.

Staff-Surgeon Dr. Jahn, of Stargard (*Der Feldarzt*, no. 1, 1876), thus speaks of the physiological action of salicylic acid.—1. In daily doses of from 4 to 8 grammes (1 and 2 drachms), salicylic acid is an excellent antipyretic, surpassing the cold bath always, and quinine in certain circumstances. 2. After producing slight and very transient phenomena of noise in the ears and slight congestion, its administration is followed, in a time varying from twenty minutes to two hours, by profuse perspiration, which lasts from four to eight hours. 3. With the commencement of the sweating, a rapid fall of temperature sets in, amounting in some cases to more than 3.6° Fahr. in two hours, and in others from 1.8° to 3.6° and more Fahr. in from three to five hours. This action is most constant and marked, when 6 grammes (1½ drachms) are given in the evening at the commencement of cases of remittent typhus; it also appears constantly after an evening dose, when there are no remissions, and continues; the action is increased by a large evening dose following a small morning dose. In most cases, however, the evening exacerbation can be prevented by a large morning dose, and if this be followed by a smaller dose in the afternoon, a considerable evening remission may be produced, which will continue until the next day. The action of the remedy lasts from four to twenty hours. 4. After the outbreak of perspiration, and with the first fall of temperature, the previously restless and agitated patients become tranquil; they sleep with deep, often stertorous, inspiration, from two to eight hours. This sleep is not the result of narcotic action, but of the exhaustion which necessarily attends a high degree of febrile action. 5. The pulse is reduced by ten, sometimes by twenty or twenty-four beats; the respirations are reduced by four to twelve. 6. Irritation of the mucous membrane of the digestive canal was observed after the administration of the drug profusely suspended in water; if it were not properly mixed, so that lumps stuck in the throat, any soreness of the throat that was present appeared to be somewhat increased. In such circumstances, the irritation of the throat by the foreign body now and then produced vomiting, which, however, did not interfere with the administration of another dose

some hours afterwards. There was no pain or burning in the stomach; nor, in two necropsies which were made, were there any signs of erosion of the œsophagus, stomach, or duodenum. 7. Salicylic acid appears to exercise a very favourable influence on the mucous membrane and muscular structure of the intestine, as in six cases of severe typhus (enteric) there was no diarrhœa, nor any great amount of meteorism. Most of the patients had but one loose stool daily, which at the end of a week became partially solid. 8. The cost of salicylic acid is much less than that of quinine; the daily dose of the latter rating, on an average, 1½ mark (1s. 6d.) while the former costs 0.4 mark.

Ad. Nathan (*Dissertation*, Kiel, 1875; and *Deutsche Zeitschrift für prakt. Medicin*, no. 2, 1876) has used salicylate of soda in twelve cases, viz., nine of enteric fever, one of pulmonary phthisis, one of osteo-myelitis of both tibiæ, attended with severe traumatic diphtheritis, lymphangitis, lymphadenitis, and diphtheritic affection of the throat, and in a case where partial subperiosteal resection of the vomer was undertaken. The results which he obtained were as follows. In all cases, without exception, the temperature, which was often excessively high, was reduced by salicylate of soda. The eminently antipyretic action of this remedy was only produced by large doses, which were repeated at short intervals. The author gave eight grammes (two drachms) to a not very strong woman, and would give even a larger dose if circumstances demanded it. If a sufficient remission of the symptoms were not produced in two hours, a similar or even larger dose was given, and repeated until an effect was produced. When the temperature had become normal or subnormal, smaller doses generally sufficed to prevent it from returning to its former height. As soon as a temperature of 39° Cent. (102.2° Fahr.) was reached, or even sooner, Nathan gave from one to two drachms of salicylate of soda to adults, and correspondingly smaller doses to children, and thus in most cases obtained a reduction to the normal. Sometimes, however, the dose had to be repeated in two hours. As with quinine, in cases of high temperature, a better result was produced by one large dose than by a number of small ones given at intervals.

The antipyretic action of the salicylate of soda was most strikingly shown in one of the cases of enteric fever. When the patient was first seen at 3 P.M. the temperature was above 106° Fahr. At 7 P.M. the first dose of 1½ drachm was given, and repeated at 2 A.M. At 8 A.M. the temperature had fallen to 101.2° Fahr.; it then increased, although two drachms were given at 9 o'clock, until at 2 P.M. it reached 106.8° Fahr. A dose of two drachms was then given, and one drachm two hours afterwards. The result was a fall of temperature to 97.16° until 8 A.M.; and it did not rise above the normal during the whole of the following day. In this case, the remissions were of long duration. That the reduction of temperature depended on the salicylic acid was proved by the fact that, when the medicine was omitted for one day, it rose to 106.16°. After this, several large doses were quickly given, six and a half drachms of salicylic acid being taken in twelve hours.

As with many other remedies, the susceptibility to the action of salicylic acid varies in different individuals and even in the same person. In children under one year, Dr. Nathan advises to begin with

half a gramme ($7\frac{1}{2}$ grains); but in the case of a child six months old, where this quantity produced no result, he gave a whole gramme an hour afterwards. For adults, the minimum dose appears to be generally a drachm. The salicylate of soda was always given in the form of aqueous solution (one part in four or five of diluted water). Although the taste of this is not remarkably pleasant, it is readily enough taken even by children.

In a case attended with hectic fever, the salicylate of soda produced perspiration, after which the patient felt more comfortable than before; and this feeling of comfort was marked in all the cases where the temperature fell to or below the normal after the administration of salicylate of soda. In cases of high fever, the reduction of temperature was followed by refreshing sleep, the patients feeling apparently well on awaking.

Very soon after the administration of the medicine, even before there was a perceptible fall of temperature, a remarkable retardation of the movements of the heart was produced. With the fall of the pulse, the arteries became more full and tense. In one case, the pulse, from being 136, small and weak, fell in the morning to 88, and in the evening to 60, becoming strong and full. From this action of salicylate of soda on the heart may, perhaps, be derived an indication for its use in cases of insufficiency and narrowing of the mitral valve. As regards respiration, the respirations were deepened in the cases observed, but there was little or no increase in frequency. After eight or twelve hours, the breathing became perfectly quiet and normal.

Dryness of the tongue was observed in some of the cases in which salicylate of soda was given; but this is observed in enteric fever. In four cases there was vomiting, but this ceased when the patients lay perfectly quiet and the medicine was given to them in the recumbent position. Nearly all the patients complained of noises in the ears and slight deafness; but these symptoms soon disappeared. In some cases they were entirely absent. Pain in the stomach, which has been observed after large doses of salicylic acid, did not occur. In four necropsies the mucous membrane of the stomach was found unaffected. In the cases of enteric fever treated with salicylate of soda there was no more diarrhoea; when any was present, it generally soon disappeared, as did also the concomitant bronchial catarrh.

As regards the intellect, Nathan says that it was generally clearer than before. In one case, a fresh increase of temperature was attended with moderate delirium; while in three other cases of enteric fever in the Kiel hospital violent delirium appeared in a few days.

The author regards the salicylate of soda as preferable to quinine, digitalis, and veratria; it can be given in rapidly repeated doses without danger of cumulative action, and does not produce dangerous after-consequences.

Köhler of Halle describes in the *Centralblatt für die Medicinischen Wissenschaften*, nos. 10 and 11, 1876, the results of an investigation of the physiological action of salicylic acid and salicylate of soda.

Injection of a solution of pure salicylic acid (1 in 300) into the jugular vein of a rabbit produced a fall of the blood-pressure, the curve being closely similar to that following the injection of large quantities of solution of chloral. This reduction of pressure occurred also after division of the vagi and of the spinal cord. Injection of solution of salicylic

acid (1 in 300) into the stomach through a flexible catheter produced no result in rabbits and small dogs, neither lowering the blood-pressure nor rendering the pulse slower. Injection into the jugular vein of solution of salicylate of soda (in proportions varying from 1 in 90 and 1 in 60 according to the size of the animal) produced slowness of the pulse and fall of the blood-pressure. When salicylate of soda was introduced into the stomach, marked results were obtained.

Respiration was retarded both by salicylic acid and by salicylate of soda; when the latter was injected into a vein, the first effect was acceleration of the breathing. The retardation of the respiration was more marked after section of the vagi.

The administration of salicylic acid or salicylate of soda produced a marked reduction of temperature.

L. Riess (*Berliner Klinische Wochenschrift*, nos. 50 and 51, 1875) gives the results of more than 400 observations on the internal use of salicylic acid. He used the pure acid for a short time, but in most of the cases gave salicylate of soda; five grammes of salicylic acid being given in a solution of phosphate or carbonate of soda. It was observed that the temperature was reduced by this dose, even when there was no pyrexia. In twenty-three cases there was an average reduction of 0.9° Cent. (1.62° Fahr.) in from four to six hours; the pulse remained unchanged as to number.

In febrile cases, the fall of temperature amounted to 2° , 3° , and even 5° or 6° Cent., often in one or two hours. The action was slight and of short duration in proportion to the intensity of the fever; and it was especially weak towards the termination of fatal cases, so that the degree of action produced by the remedy was an element in prognosis. In favourable cases, the normal temperature was reached in twenty-four hours. The result was especially well marked in enteric fever, of which 260 cases (209 of them being recent) were treated. The temperature was taken every two hours; and whenever it exceeded 102° Fahr., the above-mentioned dose was given. The first dose was sometimes insufficient. In cases of moderate severity, one dose every twenty-four hours was generally sufficient, and, from the middle or end of the second week, it was enough to give it every thirty-six or forty-eight hours. After the third week, the temperature rarely rose above 100.4° Fahr., so that at most eight or ten doses were sufficient to reduce the temperature to normal. The frequency of the pulse remained unaltered in a remarkable manner; it often remained at 130° or more when the temperature had fallen to 98.6° or 96.8° or even lower. On the other hand, the pulse often became stronger, and exhibited dicrotism less frequently than generally occurs in enteric fever.

The administration of the medicine was rarely followed by unpleasant consequences; these consisted in congestion of the head, noises in the ears, and muscæ volitantes. In some cases there was mental excitement. Vomiting was very rare, and symptoms of collapse were observed in three cases (two of phthisis and one of pneumonia). Perspiration was frequently produced, sometimes very profuse.

In the more severe cases and those complicated with cerebral symptoms, baths were used along with the salicylic acid; and under these circumstances the action of the baths appeared to be greater and more lasting than when they were used alone.

Although the enteric symptoms generally continued in spite of the reduction of temperature, the duration of the disease was generally shortened. In 166 cases which were admitted early and ran a favourable course, the average duration of the febrile stage was 13.1 days. The character of the epidemic was very severe, and the mortality great. Of the 260 cases, 63, or 24.2 per cent., died.

The elimination of urea appeared to be increased, but Riess does not speak decidedly on the point.

The antifebrile action of salicylic acid was also proved in other acute diseases: in thirty-five cases (mostly severe) of croupous pneumonia, of which eleven died; in seven cases of erysipelas; and in fifteen cases of acute articular rheumatism. In the latter, the remedy appeared to have more than a mere symptomatic action. Not only was there a reduction of temperature, attended with profuse perspiration, but the pains were relieved; and of the fifteen cases, four derived lasting benefit from one dose, and three from two doses of the medicine.

Salicylic acid was given with good effect in thirty-two cases of phthisis. The effect was more certain when it was given during the natural fall of temperature.

In intermittent fever, the action of salicylic acid was very uncertain. Of nine cases, two were cured at once, and two after repeated doses; in the other five cases, quinine was necessary to complete a cure.

In the necropsies which were made, there were no signs of the lesions ascribed to salicylic acid, neither ulcerations nor erosions of the intestinal mucous membrane.

Goldammer contributes a paper on the internal use of salicylic acid to the *Berliner Klinische Wochenschrift*, no. 4, 1876. At first he used pure salicylic acid, but found, at the *post mortem* examination of a case of miliary tuberculosis, in which three drachms had been given, half-a-dozen ulcers as large as peas on the mucous membrane of the stomach. He afterwards gave it with soda in the form and quantity recommended by Riess. In the first two weeks of typhus (enteric), evening doses were most effective; in the stage of remission, when smaller doses were generally given, a full dose in the morning was useful in arresting the evening exacerbation. Goldammer agrees with Riess as to the effects on the pulse and perspiration.

Symptoms of collapse were specially noticed as after-results. In a slight form, they often occurred; in a case of miliary tuberculosis, in which the temperature fell to normal after the administration of seventy-five grains of the acid, the collapse was so severe that the patient recovered from it with difficulty; and in a severe case of typhus, in the fifth week, the patient died in collapse after a similar dose. Great caution is required in using the medicine in cases of weak heart. Of fifty-six cases of enteric fever treated with salicylic acid, seven died (three from pneumonia of the upper lobes). Goldammer did not find that the duration of the disease was cut short by the remedy.

Zimmermann (*Archiv für Exper. Pathol.*, 1875, p. 248) found in some experiments made in the Pharmacological Institution at Greifswald, on rabbits in whom fever was produced by the injection of putrid fluids, that salicylic acid given by the mouth or by subcutaneous injection had little or no antipyretic effect.

A. Bertholet, of Dresden (*Archiv der Heilkunde*, 2

and 3 Heft, 1876) has given salicylic acid with success in one case of pulmonary gangrene, five cases of catarrhal stomatitis, eight cases of aphthæ, and three cases of obstinate dysentery, occurring in children in the same family. In the last-named disease, the medicine was given in enema (2 parts in 300 of water, with wine spirit), and succeeded in all; the disease in one of the cases (a child aged six) having obstinately resisted other treatment.

Dr. F. Weber, of St. Petersburg, contributes to the *Allgemeine Medicinische Central-Zeitung*, for March 25 and 29, an article on the use of salicylic acid in febrile diseases.

A woman, aged twenty-five, had perimetritis after labour, which was for some days treated with quinine and local remedies. The fever, however, remained high; the patient had ichorrhæmia with suppuration in the joints, and delirium; and each dose of the quinine was followed by vomiting. The quinine was omitted, and a drachm of salicylic acid was given daily in five-grain doses. Chloral-hydrate was also given to relieve the head-symptoms. In the course of five days, the temperature fell from 104° or 105° Fahr. to 99°; the pulse diminished; and the cerebral symptoms almost completely disappeared in four days. Dr. Weber also reports six other cases of puerperal disease, in which the use of quinine was attended with good effect. Their characters were as follows: Metroperitonitis with endometritis and septicæmia; putrid endometritis and parametritis (two cases); puerperal parametritis; putrid endometritis; and diphtheritic endometritis. He remarks that the salicylic acid had a remarkably favourable effect on the course of these cases; the temperature being rapidly reduced and the cerebral symptoms relieved. When the salicylic acid was given in combination with quinine, the remission of the fever was not so rapid and lasting as when it was given without quinine. The administration of the larger doses of salicylic acid was soon followed by abundant perspiration, especially during the decline of the fever. Along with the salicylic acid wine and brandy were given abundantly in all the cases; and, in spite of the large doses of salicylic acid (sixty to eighty grains daily), no toxic symptoms were observed. To prevent gastric disturbance, oily emulsions were given. Pain in the epigastrium and vomiting occurred principally when the salicylic acid was given in wafers; and troublesome irritation was produced when the acid came into contact with the mucous membrane of the pharynx or œsophagus. The best form of administering the acid was found to be a solution of equal parts of phosphate of soda and salicylic acid (about one drachm in five ounces), given with a little syrup.

Dr. Weber has given salicylic acid in nine cases of diphtheria occurring in women and children. The solution above described was used; and in one case quinine was given along with the salicylic acid for the first two days. Noises in the ears and deafness were complained of by the only two adults. The gastric symptoms were very moderate, and were obviated by oily emulsions; the patients' strength was supported by cognac and tokay. In nearly all the cases there was a reduction of fever, attended with profuse perspiration. Notwithstanding that the diphtheritic process had extended widely, its further spread was arrested under the treatment, and the deposit was rapidly destroyed. In nearly all the cases there was infiltration of the submaxillary and jugular lymphatic glands, which in two cases went

on to the formation of abscess. Dr. Weber remarks that recovery occurred more rapidly under this treatment than in cases treated by the ordinary remedies.

Three cases of scarlatinal diphtheria, occurring in a woman aged twenty-eight, and two children aged five and six, were treated successfully with the above-mentioned mixtures. In one case, recovery was impeded by infiltration and subsequent suppuration of the submaxillary lymphatic glands.

Five cases of idiopathic erysipelas—the disease in four affecting the head—were treated by Dr. Weber. The erysipelas was extensive, and in the head-cases was accompanied with delirium. Four of the patients were women, aged from thirty to forty; one was a girl, aged eighteen. All were treated with salicylic acid, quinine being given with it in one case only; wine and camphor were also used, and an ointment of zinc and camphor was applied locally. The duration of the illness was less in the cases in which quinine was not given. All the cases ended favourably. In one of the cases—a woman aged thirty-two—in which a drachm of salicylic acid was given on the first day, and two drachms (through the impatience of the attendants) on the second, there were sudden collapse, with a fall of temperature to 98.25° , blueness of the hands and feet, and diarrhoea. These symptoms were relieved by strong coffee with cognac, and the diarrhoea was arrested by decoction of arnica root and calumba.

Three cases of influenza—a child aged two and two women aged thirty and thirty-five—with a temperature of 104° , and attended with angina, ozena, catarrhal bronchitis, and gastro-intestinal catarrh, were treated with salicylic acid. In all the cases the relief of the fever on the third day was attended with profuse perspiration. Notwithstanding the gastro-intestinal catarrh, the medicine was well borne.

In two cases of chronic pneumonia—in a child and a woman—in which the temperature during the febrile exacerbations exceeded 104° Fahr., Dr. Weber gave salicylic acid; the temperature, indeed, fell, but the dyspnoea and restlessness appeared to be increased. In the child the temperature fell suddenly from nearly 105° Fahr. to 97.16° Fahr.

In a case of very extensive catarrhal pneumonia, with a temperature of nearly 105° Fahr., the fever disappeared in three days after the administration of salicylic acid was commenced.

Dr. Weber regards salicylic acid as a valuable addition to the *materia medica*, especially as it acts not only as a febrifuge but as an antiseptic. Toxic symptoms are produced only when it is given in too large and too rapidly successive doses; it should, therefore, be given in moderate quantities, and any mischievous results can be warded off by the use of alcoholic liquors. The only cures in which Dr. Weber observed toxic symptoms were two in which salicylate of soda was given.

Dr. Julius Steinitz, of Breslau, writing in the *Allgemeine Medicinische Central-Zeitung* for February 13, says that he has given salicylic acid in thirty-four cases of scarlatina with diphtheritis, and eleven cases of genuine diphtheria, occurring in children. It was administered every one or two hours in doses of $1\frac{1}{2}$ to 3 grains in sugared water. Most of the cases were severe, and accompanied with much fever. All the children bore the medicine well. In some there was a little vomiting, but this

ceased after a few doses had been given. From ten to fifteen doses were usually sufficient to arrest the fever, and at the same time the diphtheritic process was almost always arrested. A few doses given less frequently completed the cure. Two of the forty-five patients died of diphtheria; none of secondary affections. No injurious effects on the digestive canal were observed. The salicylic acid did not seem to have an influence on the sequelæ of diphtheria.

Dr. Butt, of St. Gall (*Centralblatt für die Medicin. Wissenschaften*, no. 18, 1875), states he has given salicylic acid as an antipyretic with the best effect in various cases of enteric fever, erysipelas, acute articular rheumatism, etc. The dose was 1 to 2 drachms, according to the intensity of the fever. He did not find it to be followed by any toxic symptoms.

C. Moeli (*Berliner Klinische Wochenschrift*, no. 38, 1875), states that he has found salicylate of soda to be a valuable antipyretic, both in infective and in inflammatory fevers. In the milder cases, a dose of four or five grammes was sufficient to reduce the temperature; in more severe cases, a similar dose was required after a time varying from four to sixteen hours. The action was more marked if the medicine were given when there was natural fall of temperature. The antipyretic effect generally lasted twenty-four hours; so that it was possible, by sufficient administration of the medicine, to keep down the temperature during the whole course of the disease. In about half the cases, the fall of temperature was attended with abundant perspiration. No subsequent evil consequences were observed. In a few cases there was transient vomiting, but no other gastric or intestinal disturbance. The administration by enemata was less effective than by the mouth. Subcutaneous injection produced a rapid effect, but the large quantity necessary to be used was unpleasant. In six healthy persons, to each of whom a drachm was given in concentrated solution, vomiting was produced in three; and the others were troubled with nausea, etc., but were unaffected as regarded the temperature, pulse, etc. The same occurred in three others, to whom similar doses were given *per anum*.

Dr. S. Wolffberg (*Deutsches Archiv für Klin. Medicin*, vol. xvi.) found from observations made in Dr. von Ziemssen's clinic, that, when in case of typhus (enteric) salicylic acid was given in powder in a single dose of a drachm, it reduced the temperature only in exceptional cases; in doses of one-and-a-half drachm it had only a temporary effect, and none when given in repeated doses of half a drachm during twenty-four hours. He hence concludes that it has a very slight and uncertain antipyretic action. In a patient to whom salicylic acid was given in wafers, hæmorrhagic pharyngitis set in; and at the necropsy of the enteric fever patients there were found to be erosions in the gastric mucous membrane, extending in one case into the duodenum. Peculiar appearances were found in the bodies of those phthisical patients to whom salicylic acid had been given by way of experiment.

Fischer (*Deutsche Zeitschrift für prakt. Medicin*, no. 13, 1875) describes the results of the administration of salicylic acid and salicylate of soda in twenty-three cases of typhus in the town hospital of Dresden. The medicine was given along with baths, when the temperature exceeded 103° Fahr. The treatment was always commenced in the evening; in two cases doses of one to three grammes were given in rapid

succession, and continued in the morning. The acid was given in the form of powder in wafers; no irritative action was observed either at the bedside or on the *post mortem* table; the first doses were nearly always followed by considerable perspiration, and frequently by noises in the ears and difficulty of hearing. Vomiting rarely occurred; in two cases collapse followed doses of four and six grammes (1 and $1\frac{1}{2}$ drachm). Fischer found salicylate of soda to be equally effective with salicylic acid. Intestinal hæmorrhage occurred in four cases, of which two were fatal; in one case, extensive hæmorrhage was found in the serous membrane of the intestine, in the mesentery, etc. In none of the cases were there any erosions of the gastric or intestinal mucous membrane, except the enteric ulcerations. He agrees with Moeli in preferring the salt to the acid. With regard to the action of salicylic acid in other febrile diseases, he regards it as of great use in croupous pneumonia. Of two cases of intermittent fever, one was cured after the administration in all of $3\frac{1}{2}$ drachms of salicylic acid.

A. Hiller (*Deutsches Archiv für Klinische Medizin*, vol. xvi.) describes the results of his observations on the treatment of intermittent fever with salicylic acid. In seven cases the administration of from twelve to twenty-eight grammes (three to seven drachms) was successful; the febrile paroxysm was usually cut short by a dose varying from forty-five to seventy-five grains. These cases, however, were first attacks, and mild; in five severe cases and in relapses, the medicine failed, although as much as 100 grammes (25 drachms) was given in some. After large doses there was indeed an interruption of the disease, but it returned in a few days, and was then successfully treated with quinine. Even in favourable cases the duration of treatment with salicylic acid is longer than with quinine. There are also certain difficulties in the administration of salicylic acid. It is readily enough taken in water, but its great insolubility requires the use of a large quantity of water during the day, leading to increased diuresis and the rapid elimination of the medicine. Hiller found better results when it was given in powder, or in alcoholic solution (salicylic acid 10 parts, spirit of wine 15, glycerine 120). The disagreeable taste, nausea, and frequent vomiting—especially after the alcoholic solution—and especially the danger of irritating the digestive mucous membrane, are objections to its use. In three cases in which Hiller gave salicylic acid in enema, the administration was followed by severe pain in the rectum and diarrhoea, blood being discharged in one case.

Pel has published in the *Deutsches Archiv für Klinische Medizin*, Band xvii. 1876, the results of observations made in Professor Rosenstein's clinic at Leyden, on the effect of salicylic acid in intermittent fever. It was given according to the following formula: salicylic acid, one drachm; phosphate of soda, two drachms; rectified spirits of wine and simple syrup, each seven and a-half drachms; distilled water, forty drachms; to be taken in two doses, with an interval of half an hour. In other cases, bicarbonate of soda was used, and the medicine was given according to Riess's formula: salicylic acid, bicarbonate of soda, each 1 drachm; water, $12\frac{1}{2}$ drachms; syrup of orange peel, $1\frac{1}{4}$ drachm. The smallest dose during the apyretic stage was one drachm, the largest four drachms. The patients complained of the large amount of

liquid which they had to swallow, and occasionally of a sensation of burning in the throat. No mischievous effects on the pharynx or stomach were observed. The smallest dose followed by complete recovery was two drachms.

Thirteen in-patients and ten out-patients, who said that they had ague, were treated. Of the latter, three reported themselves cured, three said that the medicine had no effect, and four did not return.

Of the thirteen cases in the hospital, nine were cases of quotidian ague, one of tertian, and three of quartan. Two quotidian and one tertian were cured by the salicylic acid; no effect was observed in three cases of quotidian and three of quartan; and in five cases of quotidian a temporary effect only was produced, quinine being necessary to complete the cure.

W. Wagner, in an article in the *Journal für prakt. Chemie*, vol. ii. 1875, speaks favourably of the use of salicylic acid as a corrective of the fermentative process in cases of cancer of the pylorus, chronic gastric catarrh, and diarrhoea. In diphtheria he recommends for children who cannot gargle, a solution of two to three grains of salicylic acid in water every two hours; for older children, a gargle of 1·5 parts of salicylic acid, 15 of spirit of wine, and 150 of distilled water. He treated fifteen cases of diphtheria in this way with very favourable results; none of the patients died.

Dr. R. Buch, of St. Goarshausen, states in the *Allgemeine Medicinische Central-Zeitung* for February 26, that he has for some time treated diphtheria with salicylic acid. He uses a mixture of 5·5 parts of salicylic acid in 150 parts of a solution containing 5 parts of phosphate of soda, and gives a tablespoonful, to be swallowed slowly, every hour. This is given to children of five years old and upwards; for younger children a smaller quantity is used. At the same time, he prescribes, for children who can use it, a gargle of salicylic acid. He says that he has not lost a single case, although in most of his patients the diphtheria was attended with a temperature even as high as 107·5° Fahr., delirium, and severe epistaxis. His first case was a boy aged thirteen, who had been ill three days when first seen, and who complained of violent pain in the neck. The temperature was 106·7° Fahr., and afterwards rose to 107·5°, the fauces becoming thickly covered with the characteristic deposit. The patient had also great difficulty in deglutition, frequent epistaxis, and delirium. He treated the patient according to Hanow's plan, with a mixture containing two parts of salicylic acid, 120 of water, and fifteen each of mucilage of gum arabic and red syrup, of which one small spoonful was given every hour, the afflicted parts being also dusted twice daily with pure salicylic acid. He afterwards employed his own plan in a number of children of three years old and upwards, which he regards as possessing the advantage of being easily carried out by the patient's parents and friends.

Dr. H. Schulz, of Ehringshausen, communicates to the *Allgemeine Medicinische Central-Zeitung* for February 16 a contribution on the use of salicylic acid in diphtheria. He says that he has given it in two cases of scarlatinal sore throat in children aged ten and twelve years, and in twelve cases of primary diphtheria in twelve children aged from one to eight years. In the two scarlatinal cases and in some of the others there were extensive deposits in the fauces and adjacent parts, extending to the glottis and

nares. These cases were treated twice or three times daily in the following manner. As much salicylic acid as possible was taken up on a moistened brush, which was then applied carefully to the affected parts. In some cases it was necessary to leave the carrying out of this treatment to the attendants, after they had been shown how to do it. At the same time salicylic acid was given internally in combination with mucilage and water. The result of the treatment in ten cases in which it was employed was, that in some the diphtheritic exudation was diminished on the first day, the general symptoms in all were improved, and in some cases it was necessary to continue the local application after the fifth day. At this time the mucous membrane of the fauces was either more of a red colour, or was coated in some parts with a very fine bluish-white layer, not due to diphtheria, but, as Dr. Letzerich has pointed out, to an effect of the action of the salicylic acid on the epithelium.

In one case (a girl, aged eight), the treatment failed to arrest the formation of diphtheritic membrane, which became very extensive and thick, so that it was necessary to remove it. The patient recovered.

In three cases, the diphtheria was confined to the larynx, the symptoms being those of obstruction of the part. Dr. Schultze gave salicylic acid in mixture; but in two instances the symptoms were so severe that he performed tracheotomy; both children died. The third child probably recovered; it resided in an elevated and isolated locality, and perhaps suffered only from laryngeal catarrh.

The result of the two cases of primary laryngeal diphtheria show how powerless we are in this affection even with salicylic acid.

LEWINSKI ON THE INFLUENCE OF THE RESPIRATORY MOVEMENTS ON THE LOUDNESS OF PERICARDIAL FRICTION-SOUNDS.*

Skoda (*Percussion und Auscultation*, 6th edition, p. 226) has observed that friction-sounds originating in the pericardium are often either increased or diminished by the respiratory movements. Traube (*Gesammelte Abhandlungen*, vol. ii. s. 463), commenting on this, remarks that pericardial murmurs, unlike endocardial ones, often exhibit the peculiarity of being strengthened by inspiration. The following case, in which the exocardial sounds were, on the contrary, increased by expiration, is therefore of some interest.

Albertina A., aged sixteen, had suffered from chorea for some time, at the age of thirteen, and after that from a variety of ailments which proceeded from heart-disease (a combination of mitral stenosis with insufficiency of the aortic valves). In November 1874 she had an attack of acute multi-articular rheumatism, complicated by pericarditis. She was taken into an infirmary, and after a few weeks the acute mischief subsided. Soon afterwards symptoms pointing to insufficiency of the cardiac muscles (diminished diuresis, palpitation, dyspnoea, etc.) showed themselves. These were relieved by the use of wine and digitalis, but she was unable to resume her former occupation. About the middle of March 1875 she suffered from fresh pain in the chest; and on March 27, Dr. Lewinski found her

complaining of great pain, which was localised in the neighbourhood of the apex-beat, where even moderate pressure gave her pain. The apex-beat was strongest in the fifth costal interspace, an inch and a half to the left of the nipple. There was a slight diffused tremor all over the cardiac region. At the apex-beat there was a strong systolic thrill. The cardiac dullness began at the lower edge of the first rib, was quite complete at the lower border of the second, and reached to the top of the sixth rib. Towards the left it passed two fingers' breadth beyond the left mammillary line; towards the right, about an equal distance beyond the right border of the sternum. Auscultation revealed at the apex a triple friction-sound—a very clear systolic one, and two somewhat weaker diastolic (diastolic and præstolic). Higher up, the sounds were somewhat softer, and here, during the systole, a slapping sound was audible. Over the third left rib, and in the second left intercostal space near the sternum, a loud systolic sound, as well as a weaker diastolic one—masked, to a great extent, by two loud rubbing sounds—could be heard. These frictional or rubbing sounds were peculiar, in being much more loudly heard during expiration than during inspiration. Their character, too, was more rasping during expiration. The cardiac sounds, on the contrary, were certainly not so loud during expiration, indeed rather less so. The rapidity of the heart's action, and the numerous sounds to be disentangled by the ear, rendered this point a difficult one to decide. There were no respiratory sounds to be heard over this region, even during deep inspiration. The dullness, too, was absolute on percussion. Pulse 116, small, and of medium tension. Hardly any fever was present. From March 30 to April 2 similar observations were made. On April 13 all friction-sounds had disappeared, and the patient sat up for some hours daily, which was probably imprudent, since the præcordial dullness, though diminished, was still excessive; and on April 17 Dr. Lewinski was called in and found her in a moribund state, with a pleuritic friction-sound, bronchial râles, and great dyspnoea. In spite of strong stimulants she died on April 18, 1875, at 5 A.M.

At the *post mortem* examination the anterior edges of the upper lobes of both lungs were found united to the pericardium by old and firm adhesions—particularly near the apex of the heart; yet a considerable portion of the pericardium was uncovered by lung (so that still more would be uncovered in the act of expiration).

The adhesions between the lateral and posterior portions of the pericardial sac and the lungs were not so firm, and were easily parted by the finger. The pleuræ were thickened in these adherent parts. The lungs were tolerably healthy. Both layers of the pericardium were changed into a firm connective tissue, and were united to each other by a recent deposit of fibrinous nature, arranged in a sort of coarse network. The cavities of the heart were considerably dilated; there was stenosis of the mitral valve, though not extreme; and the aortic valves were thickened and retracted. There were signs of two attacks of pericarditis, and two of pleurisy.

The chief interest of the case lies in the increased strength of the pericardial friction-sounds during expiration. Dr. Lewinski remembers that in the first attack of pericarditis in 1874 it was during inspiration that the friction-sounds were loudest. In the latter attack it cannot be said that the loudness

* *Berliner Klinische Wochenschrift*, no. 5. January 31, 1876.

of the inspiratory sounds masked the friction, since there were no breath-sounds heard over the dull region, and the section shows the reason. Dr. Lewinski thinks the influence of respiration on pericardial friction-sounds, in causing them to become stronger, is a point of diagnosis between them and endocardial murmurs, which are usually weakened by respiration. Reference is made to Friedreich (*Herzkrankheiten*, p. 82), and to Traube (*loc. cit.*), who says that, when the anterior edge of the left lung is adherent, endocardial murmurs become louder during inspiration, which he attributes to a more energetic contraction of the muscular fibres of the heart. Thus another means of diagnosis between exocardial and endocardial murmurs is afforded us.

[The translator thinks that a great deal depends upon the condition of the respiratory muscles and organs; and upon the tension of the air within the thorax. In the case reported the subject was young, with healthy lungs; and the tension was presumably greatest in expiration.—*Rep.*]

W. BATHURST WOODMAN.

ON A FREQUENT AND NOTEWORTHY COMPLICATION OF DIABETES MELLITUS. BY DR. RICHARD SCHMITZ OF NEUENAUH.*

When well-marked diabetes mellitus has existed for a long time, symptoms set in which are very often attributed to a congested state of the brain, but are, in reality, due to quite a contrary condition. Besides much shortness of breath, and loss of appetite, which often sets in suddenly, there are giddiness, somnolence, light-headedness, tendency to syncope, vomiting, sometimes convulsions, and transitory symptoms of paralysis. These symptoms are both excited and aggravated by exercise, whilst absolute rest in the horizontal position and stimulants either diminish or entirely remove them. These patients have a small soft pulse, which is sometimes very rapid, at other times remarkably slow, and sometimes intermittent. Respiration is generally quickened, occasionally quite normal. The impulse of the heart is always very weak, and the apex-beat is scarcely to be felt. The sounds of the heart, over that organ and in the great vessels, are weak, and by no means clear. The first sound of the heart is often scarcely to be heard at the apex, sometimes not to be heard at all. Such patients often die quite suddenly; but for the most part, after these symptoms have lasted for some time, they fall quite unexpectedly into a comatose condition, from which they never awake. It may easily be understood that in such cases we frequently, if not constantly, have to deal with considerable depression of the power of the heart, and that this is only the expression of a totally exhausted heart, the subject of fatty degeneration. In long-standing cases of diabetes mellitus such a condition of things is not only rather common, but easily explicable. If we consider the accidents to which a much weakened heart, which has undergone fatty degeneration, is exposed, we can easily understand why so many diabetics die suddenly. But it will be allowed at the same time, that such a condition deserves careful attention and study. Amongst 109 diabetics who came under Dr. Schmitz's own observation and treatment, he says that he could discover in 80 of them the objective symptoms noted above of an enfeebled heart. The subjective symptoms were entirely

absent in a few of these, but existed in greater or less degree in the great majority. Twelve of these 80 diabetics died in their own homes very suddenly. According to the medical men who attended them, death occurred in three of these twelve not only suddenly, but unexpectedly. In nine, however, there were previous symptoms of slow development of cardiac paralysis or enfeeblement. In all, subjective and objective symptoms of an enfeebled heart had existed previously. In eight of them it was quite clearly shown that corporeal exertion of different kinds had been made a short while before the sudden death. In two patients who had over-taxed the powers of their hearts by a very fatiguing journey, Dr. Schmitz observed a high degree of insufficiency of cardiac action. His urgent counsels to rest the overworked organ were unfortunately not attended to. In consequence of this neglect, the patients suddenly collapsed, and in spite of the strongest stimulants, died almost immediately. [There was, unfortunately, no *post mortem* examination in either case. In both cases, the urine passed a few days before death was free from sugar.] In seven other cases, bodily exercise increased these symptoms in a degree which threatened to be fatal. But absolute rest in a horizontal position, and the use of stimulants, caused the threatening symptoms to disappear. Two of the cases are very interesting, and are briefly subjoined.

CASE 1.—Herr M., previously quite healthy, and with no history of diabetes in his family, received in April 1872 an extremely painful wound in one foot. Although after some time this healed up, he stated that he had never been quite well since. He became thinner, and was soon tired; severe thirst and polyuria set in; and in August of that year the urine was found to be very rich in sugar. The patient was sent to Dr. Schmitz by Professor Rühle of Bonn, and came under treatment on June 25, 1873. He was twenty-four years old, and his face appeared sunken and apathetic. He seemed indifferent, and only answered questions when they were repeated several times. He had no vision with the left eye, and very imperfect sight with the right one (cataracts). He felt very weary, quite unfit for work, and was fatigued by only walking two or three steps. His breathing was very quick. He slept a great deal, and very soundly. He complained of great bewilderment in his head, and of giddiness; on account of this he could not think clearly: he sometimes lost consciousness. These symptoms increased whenever he made the least exertion, and diminished when he rested for some time. He had much thirst, but very little appetite; his digestion was very irregular, and there was often a tendency to diarrhoea. His skin was very dry and harsh. He had scarcely any fat or muscle. The mucous membranes were very anæmic; tongue quite dry, and furred; the mouth had a strong fetor; pulse 94, small, and intermittent; he weighed only 105 pounds. He had lost 30 pounds in weight in four months. There were no special physical signs of lung-disease. The cardiac impulse was strikingly weak, scarcely to be felt. The heart-sounds were very faint and feeble, especially the first sound. The liver and spleen were normal. The day-urine was pale yellow, faintly acid, sp. gr. 1030, percentage of sugar 4.8; no albumen. The night-urine was clear yellow, same sp. gr., same reaction; percentage of sugar 4.0. The amount in twenty-four hours was 3,740 c. c. m. = 131½ ounces. The treatment consisted in absolute rest in a horizontal position; rigorous antidiabetic

* *Berliner Klinische Wochenschrift*, Jan. 31, 1876, no. 5.

diet, stimulants, and nourishment alternately; as a drink 6 or 8 glasses of the Sprudel (Neuenahr) water; mild chalybeates, and ethereal tincture of castor. On July 7, the first sound of the heart could be heard plainly. Pulse 80, not intermittent. He was better in every way. The urine was of sp. gr. 1026 (by day) with 1 p.c. of sugar, sp. gr. 1020 (by night) with $\frac{1}{2}$ p.c. of sugar; daily total 2270 c.c.m. = 80 ounces. By July 11 he had gained $3\frac{1}{2}$ pounds in weight. July 27. Pulse 72. He felt well, and much stronger; urine = sp. gr. 1010; no sugar; phosphates increased; daily quantity = 1400 c.c.m. = 49 ozs. By August 12 his total gain in weight was nearly 10 pounds. His diabetes had vanished. Pulse 76, and strong. Professor Saemisch of Bonn operated successfully on the cataract of the left eye, and in October of the same year the patient was reported as quite well.

CASE 2.—Herr L., aged fifty-seven, came under treatment in August 4, 1874. He did not know whether his parents suffered from diabetes. He was much bent in walking, and his steps were slow and uncertain. His face had an anxious expression, and was rather flushed. The skin was dry and withered; the muscles and fat almost entirely deficient. Pulse 88, very weak, and almost imperceptible. Temperature not elevated. Tongue dry and coated. The mucous membranes were very anæmic. There was a strong *factor ex ore*. He complained much of weakness, and of shortness of breath. He had a great inclination to sleep, which was very heavy. He was often seized with severe vertigo. The head was very heavy and stupid. No appetite. Thirst tormenting. On examination the lungs were found healthy. The cardiac impulse was very weak, and the apex-beat scarcely felt. The first sound was scarcely heard. The liver and spleen were normal. He weighed 108 pounds; he had lost much flesh the last year or two. The day and night urine had a sp. gr. of 1044, and contained 8 per cent. of sugar, but no albumen. Quantity in twenty-four hours = 5860 c.c.m. = 206 oz. The treatment was absolute rest, lying down, and highly nourishing food, good Rhine wine, Cognac, strong coffee or tea, alternating with strong broth; for thirst, cold Sprudel water. He improved much till August 7, when imprudent efforts at walking brought on a relapse. He had gone to the Spa to drink the waters. At 6 P.M. his pulse was almost imperceptible, very irregular, varying between 40 and 50 per minute. Respirations 40. Temperature 36.4° Cent. (97.4° Fahr.). His breath was very short, and muscular weakness was extreme. He was ordered carbonate of ammonia, and strong coffee, with brandy; mustard to the chest; absolute rest, etc. At 8 P.M. there was slight improvement, but at midnight he grew worse, had vomiting, and felt very ill, and faint. At 6 A.M. on August 8 (next day) he became comatose; his pulse was imperceptible, and he had tracheal râles; $15\frac{1}{2}$ grains of musk revived him for an hour, but he relapsed into coma, and died the same night. The practical lesson is—ascertain the power and condition of the heart in all diabetic cases. If we suspect fatty or any other degeneration, strictly limit all muscular movements. Nourishing diet, moderate use of stimulants, chalybeates, and residence in a pure, dry, bracing air may all do much to retard the fatal end. Urgent symptoms demand absolute rest in bed, and the use of stronger stimulants.

MAPOTHER ON TOPICAL BLOOD-LETTING.

In a paper on topical blood-letting, read by Dr. E. D. Mapother before the Surgical Society of Ireland, and published in the *Dublin Journal of Medical Science* for March, the author said that when we draw blood by leeching, cupping, or incision, to relieve hyperæmia of organs or regions, we do not expect that the abstraction from the amount of the entire circulating fluid will afford the aid which is so often given. Each leech, for instance, removes scarcely $\frac{1}{500}$ th of the total blood, and a dozen of them applied to an adult cannot be supposed to depress sensibly the general vaso-motor force. For the control of the vaso-motor influence of a special organ or region, no therapeutical agent can as yet be selected with confidence.

Topical blood-letting acts in two different ways; namely (1), by deriving from the arterial circulation of the affected part—that is, letting blood easily escape from other vessels having a common origin; and (2), by emptying the veins which carry back the blood from the part to the heart. The vessels then can resume their normal calibre, and can take up effused materials, which they do with surprising quickness.

The blood returning from an inflamed organ is that most altered by the pathological process. For this reason, and to give direct relief to the vessels of the part, we should, if possible, drain from the actual vein, or the veins with which it connects most fully and quickly, provided they be within reach.

The ophthalmic vein empties into the cavernous sinus, which connects with the two petrosal and lateral sinuses. By leeching, therefore, near the angle of the lower jaw, and over the mastoid emissary vein, we drain very directly from the eye; and there is now in St. Vincent's Hospital a man whose eye was saved from the ravages of iritis by these means. The late Professor Jacob always selected this point for leeching in ophthalmic cases. That it was the usual bleeding point in every form of disease among the Egyptians appears from the writings of Alpinus 300 years ago.

The cerebral hemispheres send their blood back by the superior longitudinal sinus, which freely communicates with veins on the septum of the nose, through the foramen cæcum, and, with those of the scalp, through the parietal foramen, about one inch and a half in front of the posterior superior angle of that bone. If delirium pointing to active, or coma to passive hyperæmia suggest blood-letting, it can be done on the nasal septum—a place from which salutary bleeding often arises. In no part of the mucous tracts are the vessels so near the surface. It may be noted that epistaxis does not occur in domesticated animals, and in their skulls the foramen cæcum (or, as it might be better named, the superior ethmo-frontal opening) does not exist. The circulation in these creatures is not urged on occasions such as arise in man's brain-work, and their horizontal posture renders valves in the veins of the head and neck useful, whereas man does not possess them. Epistaxis can never be regarded as a mere local flow, but as an escape for congestions of more important parts than the nasal septum. If the site of the emissary parietal veins, which is about four inches in front of the occipital protuberance, be made clear for leeches, by cutting the hair and washing the scalp, blood will freely flow.

In sunstroke and in severe concussion, it is be-

lieved that considerable and sudden arrest of circulation occurs, and blood-letting at the above-named points would be indicated.

Extensive and promiscuous leeching of the scalp can only act in the way of general blood-letting.

If hemiplegic symptoms show that the base of the brain needs depletion, leeching over the mastoids will give any amount from the lateral sinuses. Otitis is relieved in the same way, as all the blood of the organ of hearing escapes by the same channel. The spinal veins are so intricate in their communications, that depletion of any of them may be easily secured by drawing from the skin over any part of the vertebral column. The ready action of irritants like blisters or depressants, like cold in the same region, may be similarly explained. The great drain which aspiration to the chest secures might be utilised in head and spinal congestions by augmenting inspirations in the way suggested, for drowned persons, by Silvester, even if the patient were comatose.

The face and neck are more easily drained of blood than any other region, owing to the absence of valves in the veins; and leeches near the angle of the jaw will draw both from the sinuses and from the tonsillitic and palatine veins, all of which freely communicate with the pterygoid plexus. If, however, a congested or oedematous spot along the mouth, pharynx, or larynx, can be reached, the scarificator is to be trusted.

The difficulties and danger of jugular venesection have banished the operation, but all its advantages can be had by leeching over the thyroid body, as the venous plexus there freely joins the superficial and deep vessels, returning from the head to the innominate veins. The rate of venous flow is here 200 feet per minute, while in remote veins it is not one-tenth as rapid. The small size and compressibility of these vessels insures that canalisation is unlikely, and the flow from the leech-bites can be easily stayed. Leeches over the sternum can scarcely relieve congestion in the larynx or trachea, while they would draw very directly if fixed near the thyroid veins. The veins from the pericardium mainly return to the internal mammary, and would be drained by leeches over the third, fourth, and fifth intercostal spaces at the edge of the sternum, especially on the left side. If, as often occurs, there be pleuritis as well, the leeches will serve a double purpose, for the pleural veins also empty at these spots. Here, also, as the arteries supplying those membranes and the veins returning their blood are so closely contiguous, local blood-letting would act in both the ways I have mentioned—the deriving from neighbouring arteries and the emptying of veins returning from the inflamed part.

The lungs, clothed with serous membranes which isolate them from the chest-walls, cannot be depleted by draining the surface of the front, sides, or lower part of the back of this region, but may on the left side, where the superior intercostal receives the bronchial veins near the fifth intercostal space. At about the third intercostal space of the right side the bronchial veins join the azygos, a trunk which has already received the intercostals and left bronchial veins. The bronchial vessels mainly supply the mucous surface, and can be drained by the sources just mentioned. The fittest site for leeching would then be over the third space, between the spine and scapula. In St. Vincent's Hospital, a girl recovering from acute rheumatism was seized with sudden and intense dyspnoea, due, it was believed, to pulmonary

embolism. Free leeching in the place indicated gave the most surprising relief. Congestion of the pulmonary circulation, such as has been often seen during the past two months of bronchitic mortality, could be better relieved by leeching over the thyroid plexus. When surgical injuries to the lungs arrest breathing power, the right heart must be distended, and thyroid bleeding seems clearly indicated. The same step seems most advisable in all those frequent medical cases which obstruct the pulmonary circulation, and overload and palsy the right ventricle. Over forty years ago Professor John Reid proved the wonderful preventive power of jugular bleeding—especially from the lower orifice—over death in drowned and hanged animals, and those poisoned by drugs which paralyse muscular tissue. At all times, blood easily passes between the right auricle and ventricle.

The abdominal wall is supplied by the internal mammary, lower intercostal, and epigastric vessels, while the organs within are connected with the aorta, portal, and inferior caval veins. They are, moreover, separated by a great serous cavity. Leeching the skin of the belly may, therefore, drain the inflamed parietal peritoneum, but cannot sensibly affect the circulation in the stomach, intestines, liver, or spleen. These organs return their blood by the portal vein, and draining it at the rectum is the fittest indication when they are congested or inflamed.

If Luschka's statement, that the umbilical vein, or ligamentum teres, of the adult is constantly pervious from the left branch of the portal to the deep epigastric, be correct, leeching round the navel may be direct and effectual in inflammations of the liver and all other organs discharging blood by the portal vein. This anatomical point, however, requires confirmation.

For acute dysentery of the tropics and other inflammatory affections of the abdominal organs, a hundred or two of leeches have been used without avail, according to writers of the last generation, while half as much blood drawn quickly from the arm produced a profound impression on the system.

There is no organ which has so special a blood-supply as the kidney. Insulated in a mass of fat, it joins no other part by vessels except on the left side of the testis, by the spermatic.

Renal congestion can, therefore, be scarcely influenced by leeching or cupping the loins; and the good supposed to follow them must be attributed to the warmth, rest, and low diet which usually are enforced, the first determining to the skin to the relief of the renal arteries; the others checking the formation of nitrogenised compounds. The labour of the organ is lessened by all these means.

The testicle returns its blood by the spermatic veins; and as these vessels pass through the groins and join the superficial veins of the region, leeching there is best calculated to relieve the organ. The veins of the scrotum return to the superficial pubic and epigastric, and puncturing them I have found valueless in cases of orchitis, whilst the risks of erysipelas or ecchymosis forbid leeches. Puncturing as deep as the tunica albuginea has been recently urged by Mr. Henry Smith, and it probably does the good by the loss of blood from the congested vessels. If the inflammation is confined to the epididymis, as is usually the case, puncturing the fibrous capsule of the body of the organ could scarcely act by lessening tension.

The anus has been often selected for leeching in hepatic congestions, but as it is only the superior hæmorrhoidal veins which return to the portal vein, any external bleeding can only be indirect. The middle and inferior hæmorrhoidal veins go to the internal iliac. In the male nothing can be more intimate than the anastomosis between the veins of the bladder and prostate and rectum, and hæmorrhage from one of these regions is often vicarious with that of the other. Mr. Fleming will recollect a case which we both saw, in which the cessation of hæmorrhoidal bleeding was followed by hæmaturia, the source of the blood being clearly vesical.

To draw blood in acute cystitis or prostatitis the surface of the rectum is the fit site; and as leeches will scarcely fix there, it is better to puncture one or two veins with a narrow long bistoury, the gut being held open by a speculum.

Concerning obstetric subjects, I always speak with diffidence. While it must be acknowledged that we have learned much from the practice of letting blood by direct incision of the womb for congestive or inflammatory affections, it appears necessary that in the case of virgins we should seek some other source for depletion—the need, on account of moral reasons, is obvious—and anatomically the uterine plexus is slightly developed in the unimpregnated, and depletion from the labia or rectum will drain more fully. Around the rectum there is a free junction between the superior hæmorrhoidal and uterine veins.

The veins in the limbs, deep and superficial, join at most numerous points, in order that the circulation shall not be interrupted during muscular action. Leeching the skin over an inflamed joint or periosteum is, therefore, the same as opening the vessels coming from the invaded part, and hence the undoubted efficacy of the measure in such cases. By the way, it is remarkable that we so rarely find the muscles the seat of inflammatory action. The rapid flow of blood, urged on by the muscles themselves, which are like hearts to the veins, may account for the immunity, whereas the fibrous tissues, sparingly supplied, are often inflamed in the subacute way, and topical blood-letting is most efficacious. When treating aneurisms by complete pressure, leeching over the sac should give aid, by lessening the tension of the arrested blood, relieving it of serum and increasing the fibrin. In cutaneous inflammations, erysipelas, acne, &c., the flow of blood and its effused fluids by incisions is too obviously efficacious to need comment.

Venesection at the bend of the elbow is almost a thing of the past, and to the question of general blood-letting I do not allude, but in severe whitlows and synovitis of the wrist-joint it gives striking relief as a topical measure.

The same may be true of opening the internal saphena vein in acute inflammation of any part of the lower extremity.

As to the modes of topical bleeding, leeching is very generally applicable, and the German practice of puncturing the left side of the animal so as to open the last of the gastric pouches—bdellotomy, as it is termed—is worthy of imitation, as blood flows far more rapidly, and the quantity is trebled from each bite. Cupping over the bites when the leeches have dropped off draws blood quicker than stuping, and the bleeding will more readily stop, for the blood coagulates, its gases being exhausted.

Still, without dread, we cannot order the introduc-

tion of leeches into the nasal, pharyngeal, rectal, or vaginal cavities; and puncturing the veinlets and aiding the flow by irrigation with warm water may be well substituted. Incisions draw blood more quickly, and the bleeding is more easily stopped. I have often bled from the nasal septum by touching the mucous membrane at three or four points with a sharp long bistoury, the ala nasi being fully everted. The curved abscess lancet, or the pointed uterine scarificator of Meyer, is in some situations more convenient. Collin's modification of Baron Heurteloup's artificial leech is most effectual on the skin, and it might be lengthened to suit for use in mucous passages. The circular shape of the blade secures cross section of the little vessels, and the pump covers six of the incisions if necessary.

Let me now recapitulate some of the organs and the superficial spots whence they may be drained:—The eye at the mastoid process and angle of the jaw; the cerebral hemispheres at the nasal septum and posterior inferior angle of the parietal bone; the base of the brain and the ear at the mastoid process; the right heart over the thyroid body; the pericardium and front of pleuræ outside the caps of the sternum; the lungs along the bases of the scapulæ, and the digestive organs from the rectum. From the veins of this gut also, those of the bladder and prostate, uterus and ovaries, can be depleted.

ANATOMY AND PHYSIOLOGY.

SCHMIDT ON THE RELATION OF THE COAGULATION OF FIBRIN TO THE CORPUSCLES OF THE BLOOD.—Alex. Schmidt (*Pflüger's Archiv*, vol. xi., and *Centralblatt für die Medicinischen Wissenschaften*, no. 11, 1876) in the first part of his communication discusses the cause of the coagulation of the fibrin of the blood. The artificial formation of fibrin from its factors, fibrinogen and fibrinoplastin (and the fibrin-ferment, which, as a rule, adheres to the fibrinoplastin), only succeeds when one of the two factors is employed in its natural solution; but the result does not take place when both substances are mixed with each other in a weak solution of caustic soda. This observation forms the basis of the new experiments of the author. In the course of his observations, Schmidt found that the presence of neutral salts is necessary for the formation of fibrin, just as for the coagulation of albumen at a high temperature. If the soluble salts be removed by dialysis from the fluids which, when mixed, yield fibrin, and if the precipitates (fibrin-forming substances) thereby deposited be brought into solution by a minimum addition of caustic soda, and the two fluids be now mixed, no formation of fibrin occurs. If, however, some of the diffusate, concentrated by evaporation, be added, fibrin is excreted. The same effect is produced by adding a solution of common salt to the extent that the fluid contains 0·8 to 1 per cent. For the formation of fibrin, therefore, a certain relative proportion of salts is necessary, and hence the reason why fluids obtained from the body after dilution with water yield no fibrin. Pericardial fluid yielded 0·132 per cent. of fibrin; diluted with an equal volume of water only 0·083 per cent.; plasma of horse's blood yielded 0·726 per cent.; diluted with one-third its volume of water, 0·689; and with an equal bulk of water, 0·617 per cent. If plasma be diluted with ten to twelve

volumes of water, only a very inconsiderable excretion of fibrin takes place, and that very slowly. If, on the contrary, chloride of sodium be added till the fluid contains one per cent. of the salt, the normal amount of fibrin is obtained. Some other salts, as is known, have the same action. Thus, by the addition of one part of a twenty-five per cent. solution of sulphate of magnesia to three or four parts of blood, coagulation may be entirely prevented, while a solution of common salt partly counteracts this effect. By dialysis of fluids which yield fibrin, the active substances are completely excreted in an insoluble form, so that the filtered fluids, on the addition of common salt, yield no fibrin, but the part remaining on the filter dissolved in weak caustic soda does.

The author then discusses the question how solutions are to be prepared which contain only one of the three factors necessary for the formation of fibrin.

1. *The Fibrin-Ferment*.—The method originally indicated by the author requires correction in one point: the alcohol must act for a very long time, three or four months, upon the albuminous coagulum. If this be not done, the solution of the ferment also contains fibrinoplastic substance, so that it can cause coagulation in solutions which contain fibrinogen alone.

2. *Fibrinogen*.—Fluids which contain this substance are much more numerous, such as the pericardial fluid of the horse, and hydrocele fluid.

3. *Fibrinoplastin* is best prepared from egg-albumen, which very rarely contains any trace of ferment. If the salts be removed by rapid dialysis, the fibrinoplastin is excreted in the insoluble form; it is then washed in water and employed either solid or in solution.

After having prepared these three substances, one may convince himself of the necessity of all three for the production of coagulation. Coagulation occurs with a neutral, feebly alkaline, or feebly acid reaction; an obvious acid reaction prevents it entirely. The quantity of fibrin obtained depends on the temperature. The physical condition of the fibrin depends upon the rapidity of its excretion. If this occur very slowly, the coagulum is very loose, breaks up easily, and is generally re-dissolved in the course of twenty-four hours, so that it entirely disappears from view. In another section, the author treats of the dependence of the quantity of fibrin on the quantity of the fibrinoplastic substance added. To equal quantities of transudations or blood-plasma—when necessary, previously deprived by filtration at 0° of colourless corpuscles—varying quantities of pure precipitated fibrinoplastin, either in the solid form or dissolved in soda, were added, and the fibrin formed was, after twenty-four hours, separated by filtration, washed with water, alcohol, and ether, dried and weighed. In the later experiments, in order to hasten coagulation, a small quantity of dissolved amorphous hæmoglobin was added. It is shown that up to a certain limit the quantity of fibrin increases with the amount of fibrinoplastin added, but not in direct proportion thereto. If too much fibrinoplastin be added, coagulation is very imperfect. Experiment II., hydrocele fluid free from fibrinoplastin, may serve as an example:

Fibrinoplastin added (f.)	Fibrin obtained (F.)	Ratio of F. to f.
1. 0.462	0.087	0.19
2. 0.924	0.098	0.11
3. 1.386	0.106	0.08
4. 1.848	0.116	0.06

The addition of hæmoglobin accelerates the excretion of fibrin, but does not increase the amount excreted. Solutions of fibrin-ferment injected into the jugular vein of the living animal did not produce coagulation, notwithstanding that the blood at first contained a considerable amount of the fibrin ferment, which had not entirely disappeared after twenty-four hours. It is therefore shown that the living organism gradually destroys the fibrin ferment, but paralyses its action in some way as long as it exists. The author then replies to Eichwald, Gorup-Besanez, and Heynsius, for which we must refer to the original. W. STIRLING, D.Sc., M.D.

MOJSISOVICS ON THE TERMINATION OF THE NERVES IN THE EPIDERMIS OF MAMMALIA.—The author's observations (*Sitz-bericht der K. Akad. der Wissenschaften*, Band lxxi.) were made on the sensitive hairless skin which covers the central part of the snout of the swine.

Nerve-fibrils from the papillæ, or direct from the cutis, enter the rete Malpighii. Some of them ascend in a winding manner towards the surface of the epidermis, becoming smaller and varicose as they approach the horny layer. Some send branches downwards, which anastomose with those which have entered at the base between the papillæ.

The fibrils that go towards the horny layer bifurcate. They do not appear to anastomose. They pass between the cells, approach very close to the horny layer, and some of them seem to end in club-shaped swellings, which are similar to those described by Cohnheim in the corneal epithelium.

After maceration in a 35 per cent. solution of caustic potash, the cells disappeared, leaving the nerve-skeleton with its branches and end-swellings intact. A corresponding arrangement was found in the epithelium of the hair-sheaths. G. THIN, M.D.

DASTRE ON THE FETAL PLACENTA OF THE PACHYDERMATA.—At a recent meeting of the Biological Society of Paris (*Annales de Gynéc.*, January 7, 1876), M. Dastre communicated the result of his researches. In the pig, the villous folds which constitute the placenta are disposed in a radiating manner around the little bald or smooth centres. The structure of the stroma of the chorion is modified at these points. Moreover, the villousities do not extend over the whole surface of the chorion: they leave free in one part and another of the middle zone two ill-determined bands. Each half of the sac of the chorion is divided into three zones: a middle zone, vascular and villous; a zone vascular only but not villous, a continuation of the former; finally, a third zone (horns of the chorion), which is neither vascular nor villous. In the thickness of the stroma of the chorion of ruminants and pachydermata, there is found, in addition, a network of chalky aspect, formed principally by a deposit of phosphate of lime. The chorion plates of this deposit are in an intimate relation with the function of the fetal placenta. But among the pachydermata they occupy the same situation as the villousities: they exist only in the middle zone. ARTHUR W. EDIS, M.D.

ROGET ON THE DEVELOPMENT OF NERVES IN BATRACHIANS.—M. Charles Roget, of Montpellier, publishes an elaborate memoir in the *Archives de Physiologie*, in which he gives a description of the first appearance of nerve-terminations in the early stages of the development of the tail of different forms of Batrachians. Having removed the epi-

thelium from the flat expansion (*membrane nataoire*) of the tail at the moment of hatching, he found, even at that early period, a complete set of cutaneous nerves, which were chiefly composed of fine moniliform fibrillæ, similar to those with which histologists are familiar in the cornea and tongue of adult frogs, and in the terminal branches of the olfactory nerves. Many of these fibrillæ present the same histological characters as the fine filaments which form the ramifications between the cells in the grey substance. These fibrillæ appear at first sight naked, but on closer examination they are found to possess a thin external coat or covering of a protoplasmic material, which here and there, at the point of bifurcation, is collected into small nodosity. The fibrillæ M. Roget regards as rudimentary axis-cylinders, of which the protoplasmic covering is the beginning of the primitive sheath. In the swellings which occur at the junctures, nuclei make their appearance apparently spontaneously (*noyaux autogènes*), without the pre-existence of any such elements; these then multiply and extend along the fibril, so as to form a continuous sheath containing nuclei. At the same time the primitive fibrillæ increase in thickness and in number, by a form of reduplication of the pre-existing fibrillæ, so that finally a compound axis cylinder is formed, which is contained in a delicate sheath of protoplasm. In some of the fibres there then appears a third element between the two pre-existing; by a form of infiltration of myaline within the delicate sheath, distinct medullated fibres are formed. These do not undergo subdivision, or apparently any further change, but the fibres which are still without medullary covering continue to increase in number and size, and by successive divisions new sets of branches are formed. The first appearance of these is always the same fine moniliform fibrilla, which subsequently increases in size. The paper is embellished by six well-executed plates.

BROWN-SÉQUARD ON THE IRRITABILITY OF THE CEREBRAL LOBES.—In the first of a series of papers which Dr. Brown-Séquard announces on the above subject in the *Archives de Physiologie*, he describes the effects of irritation of the surface of the brain with the actual cautery. From a number of experiments he comes to the following conclusions. 1. Mechanical, and more especially thermic, stimuli applied to the scalp or meninges, produce on the side of experiment the various phenomena which follow section of the cervical sympathetic. 2. The same phenomena are produced in a more marked degree when the stimulus is applied to the surface of the hemisphere of the brain. The middle lobe gives the most striking results, the anterior lobe the least so. 3. The degree of paralysis of the cervical sympathetic is in proportion to the amount of the stimulus, and to the extent of surface to which it has been applied. 4. He concludes that it is thus demonstrated that the lobes of the brain are capable of excitation by mechanical and thermic irritation, just as they are known to respond to electric stimuli.

BABER ON THE STRUCTURE OF HYALINE CARTILAGE.—Mr. E. C. Baber (*Journal of Anatomy and Physiology*, vol. x.) arrives at the following results in the course of experiments undertaken to verify these statements made by Dr. Hermann Tilmanns ('Contributions to the Histology of the Joints,' Max Schultze's *Archiv für Mikroskopische Anatomie*, vol. x. part iv.), 'that a moderately

strong solution of permanganate of potash or a ten-per-cent. solution of chloride of sodium broke up the hyaline matrix of the cartilage into fibrils undistinguishable from those of connective tissue, but that the cell-territories, shown by the action of chlorate of potash and nitric acid, did not appear, although with the permanganate solution the cartilage-cells became free and lay isolated between the bundles of fibrils.'

Mr. Baber found that sections of the cartilage of femoral condyles of a freshly killed rabbit or kitten, and of the kitten's costal cartilage, when treated with permanganate of potash solution, of strengths varying from $\frac{1}{16}$ to $\frac{1}{50}$ per cent., showed under slight pressure traces of fibrillation in four or five days, but that with solutions of greater strength the cartilage broke up without any trace of fibrillation.

Moreover, he found that the results, when the fluid was changed several times a day (a point insisted on by Tilmanns), were no better than if it were not changed at all.

In a ten-per-cent. solution of common salt, similar sections of cartilage under slight pressure presented distinct fibrillation after maceration varying from four days to a fortnight. This fibrillation was found to disappear at times whilst under observation, but could be reproduced by pressure, carefully avoiding any shifting of the cover glass, as this caused it to disappear, and it could not subsequently be remedied.

The cartilaginous expansion of the shoulder-girdle of the newt was also treated with a ten-per-cent. solution of chloride of sodium both with and without pressure, but without producing any trace of fibrillation.

The cartilaginous expansion of the shoulder-girdle of the newt, and sections of costal cartilages and cartilages from the femoral condyles of the kitten, examined in baryta water after maceration for half, three-quarters, one, one and a-half, two, and three hours respectively, presented well-marked fibrillation with pressure and occasionally without it; but it soaked for a day or more, no fibrillation was visible, except in one specimen of femoral cartilage of the kitten, which, after thirty hours' maceration, presented it well marked under firm pressure.

In lime-water, sections of the femoral and costal cartilages of the kitten, and also the cartilaginous expansion of the shoulder-girdle of the newt, showed well-marked fibrillation in the course of a few days, both with and without pressure.

Finally, Mr. Baber found that the cartilage of the femoral condyles of the kitten, in $\frac{1}{2}$ per cent. solution of sodium chloride, showed abundant fibrillation with pressure in the course of a few days.

With regard to the character of the fibrillation, the author states that it appears both complete and incomplete, both forms commonly occurring in the same specimen. When complete, it consists of a very fine but distinct more or less parallel and wavy striation, which can be traced above or beneath each cartilage-cell, as the case may be. Not uncommonly, in incomplete fibrillation, the striæ appear to run principally from cell to cell or for a short distance on one or both sides of a cell; and in this case also can always be followed either under or over each cell. He considers that this appearance may be produced thus. Assuming the cartilage-cells to be more resistant than the matrix, or at any rate to have become so by maceration (a fact which seems probable from the matrix breaking up under pressure, and allowing

the cells to escape into the surrounding medium), then those portions of the matrix situate under or over a cell will on pressure be subject to greater compression than the other parts, and it is therefore here that the fibrillation first appears.

In the longitudinal sections of cartilage from the joints, the direction of the fibres appeared to be at right angles to the joint surface, while in transverse sections they ran in various directions. Thus Mr. Baber agrees with Tilmanns that the hyaline matrix is made up of fine fibrils, cartilage-fibres, held together by an interfibrillar cementing substance which can be dissolved by certain reagents. Dr. Hermann Tilmanns, however, finds a ten-per-cent. salt solution far inferior to solution of permanganate of potash, and it is this that he recommends. Mr. Baber finds the effects of permanganate of potash solution very slight and uncertain, whereas common salt solution (both $\frac{1}{2}$ and 10 per cent.) and lime-water produced the required effect readily if followed by pressure.

The experiment with $\frac{1}{2}$ per cent. salt solution Mr. Baber lays great stress upon, as probably explaining the occurrence of physiological fibrillation of the matrix on the free surface of the hyaline cartilage of joints: for the cartilage is here bathed with synovial fluid, and pressure is applied to it by the contact of the opposing joint-surfaces:

PATHOLOGY.

COLOMIATTI ON A LIPOMA OF THE CERVICAL SYMPATHETIC.—In the *Gazzetta delle Cliniche* of February 8, Dr. Colomiatti describes certain appearances which he found in the necropsy of a person who had died of pulmonary and laryngeal phthisis. He specially examined the cervical sympathetic on both sides, some of the dorsal and abdominal ganglia, and the ganglia of the solar plexus. None of these presented to the naked eye any remarkable appearances, except the first cervical ganglion on the left side, which was about one-third larger than its fellow. It was rather soft, especially at the middle part, which appeared somewhat swollen.

Having divided it transversely through the middle part, Dr. Colomiatti found in the centre a yellowish mass as large as a millet-seed. At first he believed it to be caseous, especially as, as has been said, the cause of death was phthisis. On examination, however, he found it to be a lipoma, containing large so-called fat-cells, resembling those found in lipomata in other parts of the body. After treating the ganglion with Müller's solution for nine days, he made various sections through the tumour. The

mass, which was nearly spherical, was joined by a small peduncle to the periganglionic connective tissue, from which numerous fibrils proceeded towards the centre of the tumour, enclosing a vascular loop. Around the tumour were some fascicles of connective tissue arranged in the form of an incomplete capsule.

Dr. Colomiatti, in conclusion, remarks that lipoma in the sympathetic ganglion has not hitherto been described; and thus sums up the other appearances which he found in the ganglion under consideration.

1. Increase of the interstitial fibrillar connective tissue between the nervous elements, and especially of the perivascular tissue.

2. Irregular dilatation of the small veins.

3. Tumefaction of the nuclei, especially of the epithelioid cells lining the capsule which enclosed the giant-cells, and the frequent presence of two nuclei in their protoplasm.

4. The complete homogeneity of a large protoplasmatic zone surrounding some of the ganglion-cells, with central accumulation of pigment-granules in the same (*sclerosis*, which Lubimoff found in a case of diabetes mellitus, and in two cases of diffuse purulent peritonitis.)

5. A kind of alveolar atrophy, proceeding from the periphery to the centre, in many of the ganglion-cells, many of which were reduced to a simple protoplasmatic network, thickly pigmented, surrounding the nucleus, and containing in its meshes sometimes a few drops of fat, but generally round cells, many like migratory cells.

A. HENRY, M.D.

ORTH ON LOCALISED TUBERCULOSIS OF THE LIVER.—Two cases are recorded by Dr. Orth in Virchow's *Archiv*, Band lxvi. Heft 1, of this somewhat rare form of disease. The first is one of general tuberculosis of miliary kind in the lung, spleen, kidneys, liver, testes, and choroid. The liver was enlarged, and its section studded with small round tubercles, in great number; and, in addition, in the substance of the right lobe was a caseous nodule, of the size of a walnut. Between these two forms, the caseous and the miliary, were others which were obviously the offspring of the small simple tubercle; from which it is concluded that the yellow caseous nodule was also formed by the conglomeration of many smaller nodules.

The second case is of some practical importance, because the tumour in the liver could be felt through the abdominal wall, and thus gave rise to the diagnosis of cancer. The patient was an old and wasted woman, aged fifty-nine years. The liver contained tubercle and cheesy nodules. The portal, lumbar, and epigastric (?) glands were caseous. The peritoneum was tuberculated, and there were chronic caseous peribronchitis, brown atrophy of the heart, granular kidneys, and intestinal catarrh.

The whole of the fore border of the liver, particularly round about the gall-bladder, was implicated in an irregular bossy yellowish tumour, to which some large lymph-glands and the duodenum were united. Throughout the liver-substance were other smaller masses, and the whole peritoneum was studded with miliary tubercles. The microscopical examination left no doubt of the tubercular nature of the larger liver-tumour. From the large size of the main tumour, the still but partial caseation of the lymphatic glands, and the similarity of the microscopical appearances to those met with in yellow tubercle in the brain, the author concludes that the

disease in this case affected the liver first, and thence infected the glands in the portal fissure and behind the peritoneum.

[Both these cases, but especially the latter, are worthy of record, both clinically and pathologically. Somewhat similar ones have at times come before the Pathological Society of London, and have generally excited some discussion. The following may advantageously be contrasted with those recorded by Dr. Orth: *Path. Society Translations*, vol. ii. 182; iii. 353, 355; xviii. 142; xx. 198; xxi. 236, 372; xxv. 142; also a case in the same transactions recorded by the reporter during the present session.—*Rep.*] JAMES F. GOODHART, M.D.

LAVERAN ON REFLEX PARAPLEGIA.—In the *Archives de Physiologie* (vol. xii. p. 866, Dec.) Dr. A. Laveran, of the Val-de-Grâce Hospital, details the case of a man, aged forty, who came under observation with incontinence of urine, cystitis, incomplete paraplegia, secondary abscesses, and considerable fever; symptoms which, he considers, pointed distinctly to the diagnosis of reflex paraplegia, and not of a spinal lesion, as the most important symptoms of myelitis were wanting. After death the morbid changes in the kidney and bladder were very obvious and extensive, while the spinal cord, to the naked eye, appeared perfectly healthy. Under the microscope, however, marked atrophic changes in the nervous element were found associated with considerable proliferation of the connective tissue. The author thinks that many, if not all, of the fatal cases of so-called reflex paraplegia in which the cord is reported to be quite healthy, would probably give the same result if microscopic investigation of the cord had been adequately carried out. G. YEO, M.D.

WINSLOW ON A PECULIAR NEW FORMATION IN THE STERNO-CLEIDO-MASTOID MUSCLE OF A NEWLY BORN CHILD.—At a meeting of the Pathological Society of Philadelphia (*Philadelphia Medical Times*, February 19), Dr. W. H. Winslow asked for information with reference to this growth, seen in a newly born child. It was two-and-a-half inches long and three-quarters of an inch in diameter, cylindrical in shape, with ends slightly rounded. It was very hard, like cartilage, and could be separated somewhat from the surrounding tissues by pressing the fingers in deeply. There were no symptoms of inflammation, or other abnormal manifestations, connected with it. It was situated longitudinally along the anterior border of the left sterno-cleido-mastoid muscle, and was at first supposed to be connected with its sheath and that of the vessels beneath.

No treatment was instituted, and it gradually disappeared, until at the end of the third month no sign of its presence remained. The mother had received no injury during pregnancy; the labour was a normal and easy one, and the child was received tenderly and carefully. The mother was slightly scrofulous, but enjoyed good enough health, and had two other children living and hearty. The father was a tough Scotchman, in perfect health, and there were no possibilities of a syphilitic taint in the family. The baby was now fat and hearty, and the left sterno-cleido-mastoid was as well developed and as functionally active as the right.

Dr. Ashhurst said that the two most plausible theories which had been advanced to account for these indurations of the sterno-cleido-mastoid muscle

were (1) that the condition resulted from an injury sustained in birth; and (2) that it was a lesion of congenital syphilis.

Dr. Horace Williams said that within the past year he had had two such cases, and had been at a loss to account for them. Both were primiparous labours. One was a breech-presentation, the child being born rapidly, although the mother was forty-three years old. The second was a primipara also, thirty-nine years old, and a difficult forceps case. In the latter case, the swelling was not located over the sterno-cleido-mastoid muscle, but posterior to and below the region of the ear, corresponding very nearly to the position over which one blade of the forceps must have been. Both of these swellings disappeared, the first in eight weeks, and the second in three. Iodide of potassium in compound soap liniment was used as a local application; nothing internally. There was no discoloration of the skin in the second case, nor other condition whence it would be possible to infer that the forceps produced it. Subsequent history entirely free from any specific developments.

Dr. Ashhurst said that it was well known that similar indurations of muscle occurred in cases of acquired syphilis, particularly, as pointed out by Ricord, in the biceps.

BERTOLET ON THE REGENERATION OF NERVES AFTER EXCISION.—At a meeting of the Pathological Society of Philadelphia (*Philadelphia Medical Times*, February 19), Dr. R. M. Bertolet exhibited portions of reproduced nerve derived from the musculo-spiral and the radial. They both exhibited the button-like cicatricial neuromes, the central swelling in both specimens being markedly greater than at the distal end. The intermediate portion, *i.e.* the regenerated part, of the nerve measured over an inch in the former, and nearly two inches in the latter specimen; in both cases it presented medullated nerve-sheaths and sharply defined axis-cylinders, and was indistinguishable, microscopically, from a perfectly normal nerve, thus showing how complete the reparation has been. The musculo-spiral was primarily excised several years ago by Giuseppe Sapolini, and recently again under the direction of Dr. S. Weir Mitchell. The radial was from a case of Dr. H. Lenox Hodge, who, being present, furnished the following history.

On December 5, 1874, Dr. Hodge removed about two inches of the radial nerve on the back of the forearm, after it comes out from under the tendon of the supinator longus. The operation was done on account of long-continued and persistent pain in the back of the hand, accompanied at times with great redness and swelling. The patient was fifteen years of age. After the operation she was perfectly free from pain, and had no sensation in that part when touched. In about six weeks the pain gradually began to return; a few weeks later the tactile sensation also returned. The pain grew worse, and became as severe as at any time before the operation. Nothing gave relief, although every means were employed. As the tactile sensation had returned, as well as the pain, it was evident that the nerve had reunited, and that the pain was not merely subjective and referred to the old part. Therefore, on October 20, 1875, he repeated the operation, and found the nerve, as expected, reunited, with the bulbs of reparation as described by Dr. Bertolet. The distance between these bulbs was one inch and a quarter. At this last operation, he removed three inches of

the nerve and turned back the ends of the distal extremity so as to form a loop, and thus endeavoured to prevent another restoration of the nerve. This operation as well as the preceding was done entirely outside of the deep fascia, and therefore no motor filaments were removed, and no power or motion of the hand or fingers was wanting; nothing was lost but sensation.

HODGE ON CONGENITAL ABSENCE OF THE RADIUS.—Dr. H. Lenox Hodge reported the following case at a meeting of the Pathological Society of Philadelphia (*Philadelphia Medical Times*, February 5). The dissection and memoranda were made by Mr. T. M. Lloyd, student of medicine.

A white male subject, without any previous history, was brought to the Anatomical Rooms of the University of Pennsylvania. The body was well developed in all respects, except the left fore-arm and hand. The apparent age was seventy years.

The left arm was of normal size to the elbow, but the fore-arm was much shorter than normal, being about eight inches in length. The hand and wrist were placed nearly at right angles with the fore-arm, being drawn towards the radial side, the palm looking towards the body. The whole hand was much smaller than its fellow of the opposite side; the thumb especially was very small, its metacarpal bone lying almost in front of the metacarpal bone of the index-finger, so that it was directed towards the palm. No cicatrices were found in the skin.

Upon dissection, no cephalic vein was found, but two large veins were found on the inner side of the arm, one in the normal position of the basilic, the other accompanying the brachial artery. The brachial artery, and the median, ulnar, and internal cutaneous nerves, were in their normal positions, above the elbow; below the elbow, the brachial gave off the radial artery, a small branch going down and supplying the muscles on the outer side of fore-arm, passing over and in front of the metacarpal bone of the thumb to palm of hand. The ulnar artery, the main continuation of the brachial, supplied all the muscles on the inner side of the fore-arm, and formed chiefly the superficial and deep palmar arches of the hand. The radial nerve was not traced below the elbow. A large branch of the median supplied the muscles on the outer side of the fore-arm. The median nerve supplied the flexors, both sides of the thumb, first and second fingers, and radial side of ring-finger. The ulnar nerve supplied the flexor carpi ulnaris, and both sides of the little and one half of ring finger.

The biceps muscle of this, as well as that of the right arm, was supplied with a third head, arising from the upper portion of the shaft of the humerus, and on this side the tendon of the biceps was inserted into the coronoid process of the ulna. A flat triangular muscle, arising from the internal condyloid ridge, converged to a tendon and joined that of the biceps. A muscle supposed to be the supinator longus had a normal origin for that muscle, but extended across the elbow-joint anteriorly, and was inserted into the intermuscular septum on the inner side of the arm. The origin of the brachialis anticus was normal; its insertion was at the inferior extremity of humerus anterior to the joint and coronoid process of the ulna, beneath the insertion of the tendon of the biceps. The flexors sublimis digitorum and profundus digitorum had a common origin from the upper two-thirds of the ulna, on the inner side,

and the intermuscular septum between these and the flexor carpi ulnaris, and had normal insertions. The flexor carpi ulnaris was well developed, had its origin from the inferior extremity of the humerus, and from the whole length of the ulna on its inner and posterior surface (this was the only muscle attached to the posterior surface of the ulna except the triceps, which was inserted into the olecranon, as usual); the insertion was normal.

The extensor communis digitorum had its origin from the anterior surface of the ulna, also receiving a strong tendinous slip from the tendon of the biceps. The tendons of insertion were normal. The extensor carpi ulnaris was well developed; it arose from the upper two-thirds of the ulna, and the intermuscular septums of the triceps; its tendon passed over a groove on the inferior extremity of the ulna, and was inserted into the metacarpal bone of the little finger. The pronators and the extensors and flexors of the thumb and of the radial portion of carpus were absent. The only muscle to the thumb was a small slip, having its origin from the metacarpal bone of the middle finger.

The radial bone was entirely absent. The ulna had a well-marked olecranon and coronoid processes and sigmoid cavity, but was articulated a little nearer the external condyle than normal. The length of the ulna was seven and a-half inches, from the olecranon process to the inferior extremity; its shaft was curved, the concavity being anteriorly. The carpus was articulated on the radial side of the ulna—not at its extremity—and almost at right angles with it.

MEDICINE.

ROHLFS ON WERLHOF'S DISEASE (PURPURA).—Dr. Heinrich Rohlf, of Göttingen, publishes a very learned and critical paper on purpura in *Betz's Memorabilien* (Jahrgang xx. Heft 10), from which we extract the following. It is now more than a hundred years ago since Werlhof first distinguished this disease, and yet its nature and pathology are by no means matters of general agreement. Perhaps Werlhof's treatment by bark and acids is still one of the best methods. Dr. Rohlf says he has only met with four cases in twenty-five years of practice.

The first of these is detailed at some length. The patient, a native of Newcastle, was a delicate blonde, aged seven years. She had had measles two years before. Her parents were in comfortable circumstances. The purpura first attacked her in England a year before, and she was treated by three medical men, not one of whom had ever seen a

similar case. This first time it only lasted fourteen days. On March 14, 1854, she walked a long way to see her aunt, and was overheated. Next day she had severe epistaxis, and red spots appeared on her legs, neck, and face. The day after there were bluish-black discolorations on the legs, and dark patches on the tongue and lower lip. Fresh spots appeared from day to day, and two days afterwards there was a fresh attack of epistaxis. On the 19th there was constipation, on the 20th fresh epistaxis. There was bleeding from the mouth, and the stools were black. After getting nearly well with the use of fruits, mild laxatives, and aromatic sulphuric acid, she had a relapse about April 8 with severe hæmorrhage from the mouth. Bark was then ordered, as well as the acid. On June 1 she was cured; and, although fourteen years have now elapsed, she has had no relapse.

The next case was a boy aged three, whose mother died of phthisis. He also had an attack of purpura when two-and-a-half years old, and five other attacks (lasting three or four weeks) within the next three years. They yielded easily to bark and aromatic sulphuric acid. The boy, just before the attack, began spontaneously to nibble peat. In a subsequent attack he died rather suddenly during an obstinate attack of bleeding from the gums, apparently in a convulsion. It is somewhat singular that in this attack he could not get at any peat, and he had no medical treatment.

The third case was in a very anæmic girl, aged nine years, who had in all eight attacks. Her mother was consumptive, and died young; the father (as in the other cases) appeared strong; the step-mother was a bad manager. The first attack followed an injury to the upper jaw, which broke away a piece of it. It lasted three or four weeks. In the other attacks either violent anger or a chill preceded. Her last attack occurred at the age of seventeen, and whilst she was freely menstruating. In all these cases the patients were badly nourished and anæmic.

In the fourth case, a young girl, the child of healthy parents, was not only well nourished, but had general plethora. Few young girls are so full-blooded—her veins were full; her face, arms, and hands ruddy and blooming. She was six years old when first attacked. From 1863 to 1875 she had twelve attacks in all. During the second illness the treatment was entirely dietetic, with such success, that it only lasted eight or ten days. Twice she had epileptiform seizures after the bleedings. In the seventh attack she had severe hæmorrhage from the kidneys, twice bleeding from the ears. Ergot of rye was a great success in the treatment of the renal hæmorrhage. She menstruated at twelve years. Her two elder sisters did so at the age of eleven.

As regards the bibliography of purpura, Rohlf thinks there is no doubt that Werlhof was the first to describe it as a special disease. He gave it the name of 'morbus maculosus hæmorrhagicus.' Rohlf thinks this name preferable to the pleonastic 'purpura hæmorrhagica' of Lebert, or 'petechiæ sine febre' of others, especially as there may be fever during the course of the disease. Schönlein gives the name of 'peliosis,' and distinguishes peliosis Werlhofii, rheumatica, and senilis. Hebra reckons this disease amongst the symptomatic hæmorrhages of the skin. This classification into idiopathic and symptomatic seems illogical. However, Hebra makes the following varieties: Purpura

rheumatica, P. simplex, P. papulosa, P. hæmorrhagica. Watson (*Principles and Practice of Medicine*), like most modern authors, describes the disease under the name of purpura, and justly remarks that it ought not to be classed as a skin-disease.

As regards its etiology and pathological anatomy, there is a very wide range of opinions. Bischoff ascribes it to 'a relaxed condition of the arterial and venous capillaries, allowing the blood, as it were, to sweat through;' but he allows that the composition of the blood may be at fault, as in scorbutus. The unknown author of a book, called *Recepte und Curmethoden der besten Aerzte aller Zeiten* (Leipzig, 1810), says that for him scurvy and purpura are quite identical. Alibert says that 'purpura is a disease of the rete mucosum of the skin.' This can scarcely be true, since the Malpighian layer is not vascular. Hufeland classes this disease, which he calls hæmatosis, with hæmophilia. Behr (Schmidt's *Encyklopädie*, Band i. p. 585) considers the essence of purpura to be a morbidly excited venosity, a disease of the superficial veins of the skin. Behrens believes it to be a blood-disease, not identical with scurvy. Reil sees in it a paralysis of the terminal arteries. Raimann admits debility of the arterial and absorbent vessels. August Hecker, Senior, and Jaeger consider it a modification of scurvy. Kreysig considers it to depend on disease of the portal vein. Puchelt also attributes it to increased venosity! Bateman considers the disease to be an extravasation beneath the cuticle from the terminal capillaries. He found the spleen much enlarged in a fatal case. Wunderlich admits that there are cases of purpura closely simulating scurvy, although typical cases may differ. Wolf (of Warsaw) again inclines to paresis of the terminal ends of the cutaneous vessels. Dr. Henning (of Zerst, see *Hufeland's Journal*, Band vi. p. 49) attributes the disease not to the blood in general, but to the solid tissues. Fuchs says that 'the disease is generally found in lower-class people who live in small damp dwellings, and are badly nourished.' Felix Niemeyer attributes the morbid condition of the capillary walls to malnutrition, from an insufficient and faulty diet. Watson considers it identical with scurvy. Canstatt is the first to recognise two distinct varieties of purpura; and Marx justly says that the transpiration may as well occur in an inflammatory as in a debilitated state of the blood. Andral had already observed that a great increase of red blood-corpuscles may be a cause of apoplexies and hæmorrhages. Baumgärtner does not admit that purpura always originates like scurvy. He noticed a case in a strong person from suppressed catamenia, which was cured by a bleeding. There is considerable discrepancy as to the pathological anatomy and the constitution of the blood. Thus the extravasations have been found close under the epidermis, partly in the true skin, partly in the subcutaneous areolar tissue; yet there has never been found any inflammatory appearance around the hæmorrhages.

Biet, Rayer and Franz Simon found scarcely any fibrine in the blood, whilst the proportion of corpuscles was nearly normal. Albers (of Bonn), however, noticed the blood coagulate as in health. So did the author in cases 1 and 4, not in 2 and 3. Rokitsky says the petechiæ and ecchymoses are due to decomposition of the blood, and he will not allow them to be really hæmorrhages, but only the transpiration of 'coloured red serum without simul-

taneous extravasation of blood corpuscles.' Stark considers it an efflux of blood in the cellular tissue of the skin and mucous membranes. Wagner says 'small purple-red hæmorrhages under the skin are called purpura. They presuppose a solution of continuity of the walls of the vessels.' Voigtel denies that the petechiæ occupy the Malpighian layer. Andral denies that they are in the sub-mucous connective tissue. Kunz says the hæmorrhages are at varying depths and in different layers of the skin, etc. He says they are found in all the digestive tract, seldom in serous membranes, and seldom in the bronchi. They are not uncommon in the liver, spleen, and parenchyma of the uterus. Watson's views are well known. Bock classes purpura with septic fever and scurvy, and says it is due to a special dyscrasia. The blood is thin, poor in fibrine, and although the corpuscles are numerous, they are partly disorganised. He holds that there is a lesion of blood-vessels. Most pathologists hold this view as to the blood-vessels. But Stricker and Cohnheim have lately lent fresh support to the old views of hæmorrhage *per diabrosin*.

As regards the diagnosis, Wichmann, who writes well on this, errs in denying that the disease may be epidemic—though this is rare—and again in limiting the form of the hæmorrhage and its sites. We may have vibices and ecchymoses; and blood in the urine and fæces is common. The form of the spots may vary. Their colour may be black as well as red. Hæmophilia has bleedings without the spots. The spongy gums of scurvy are not so common in purpura. Again, the exudations amongst the muscles, and the serous hæmorrhages distinguish scurvy. The peculiar fever distinguishes typhus. Scurvy is most common in winter or early spring, and purpura in summer and autumn. Authors differ much as to the frequency of purpura. Henning (Zerbst) practised sixteen years without seeing a case, then one occurred in his practice. Many writers consider it rare. There is pretty general agreement amongst the best authors as to the therapeutics. Werlhof wrote 'acida primis diebus, mediis emulsionibus, postremis corticem adhibui.' He sometimes gave opium with acids and bark—'ut metuenda humorum exsolutio compescatur et fibrarum moderetur irritatio motusque inequalis.' Wunderlich is sceptical as to treatment. Parry was first to propose bleeding. Yet Hebra justly says however good the theory of venesection may be, it is seldom applicable, since the majority of cases are asthenic. Quinine is far inferior to bark. The bowels and diet must be regulated.

The views here expressed may be summarised thus.

1. Purpura is best named as it was by its first discoverer, Werlhof.

2. The source of the hæmorrhages is the capillaries of the skin and mucous membranes, not the Malpighian layer, though the blood may invade this.

3. Purpura is neither scorbutus nor hæmophilia.

4. We have no certain knowledge of the chemistry of the blood in this disease, yet a dyscrasia is probable.

5. There are two forms, an asthenic like cases 1 and 3, and a sthenic like case 4.

6. The cause of the former is probably an altered and impoverished condition of the blood; but diet, cold, over-heating, anger, and excitement, are predisposing causes.

7. The vessels may or may not be lacerated,

hence the extravasations differ in colour, etc. Purpura is a bad name, as pointing only to arterial lesion.

8. In the sthenic or plethoric form the blood is probably too rich in fibrine, and perhaps in corpuscles. In this form there is no disease of the walls of the capillary vessels, the lesion in these being purely mechanical. This form can easily be distinguished from the other by the pulse and the general habit of body.

9. It is only in this sthenic form that blood-letting can find any place in our repertory of remedies.

10. The dietetic as well as medicinal treatment of the two kinds is essentially different. Werlhof's treatment is adopted for the asthenic form of purpura. In the sthenic form expectant treatment is most suitable, and active medicines should only be used when the bleedings are so severe as to induce convulsions, or the induced anæmia threatens collapse, or when some organ like the kidney or lung begins to bleed.

11. The spots in purpura often appear first on the neck, face, and arms, not on the legs, as is often said. It was so in Werlhof's first case (*Opera Omnia*, vol. iii.)

12. The explanations given by Rindfleisch (*Lehrbuch der Pathol. Gewebelehre*) of punctiform hæmorrhages in the brain, viz., atheromatous processes, inflammatory hyperæmia, and embolisms, are not improbably equally applicable to the skin and mucous membranes in purpura. There may be different processes, which it is worth while to study, both clinically and anatomically.

WIDMANN ON INSUFFICIENCY OF THE AURICULO-VENTRICULAR VALVES WITHOUT DEGENERATION, AND ON STENOSIS AND INCOMPETENCY WITHOUT MURMURS.—In the *Allgemeine Wiener Medizinische Zeitung* for October 12, 1875 (no. 41), and following numbers, there is a paper by Dr. O. V. Widmann on the above subject. He draws attention to the frequency of mistakes in the diagnosis of valvular disease of the heart. Murmurs are heard in life, and no lesion is discovered after death. Physiologists and clinical observers are now pretty well agreed as to the cause of the normal sounds of the heart. They are not so unanimous as to the cause of murmurs heard over the cardiac valves, and produced during the heart's action. Skoda and the old German school attribute them all, organic, and inorganic or functional, to friction of the blood. The French more justly attribute many of these to the narrowing or stenosis of the blood-channels setting up waves, the friction of which gives rise to sounds of various kinds. Lateral pressure is also caused by whatever narrows the channel, and this is greatest just in front of and behind the obstruction. The speed of the stream is increased just in front of the stenosis, and the stream tends to spread itself out the moment it has passed the narrowest point; at the same moment the walls of the blood-vessel, when the tension has reached its maximum, tend to approximate again by virtue of their elasticity; and hence secondary vibrations are induced. Thus the production of murmurs in cases of *stenosis* is clearly explicable by ordinary physical laws. In cases of *regurgitation*, the blood being driven with some force through the chink of the valves which do not close properly, doubtless sets the edges of the valves into vibration, just as a current of air does a metal tongue in musical instruments and toys. Thus, to produce a cardiac mur-

mur, the necessary conditions are—(1) A certain force and swiftness of the blood-stream; (2) A certain degree of narrowing of the vessel, or of the chink (or ostium) through which the blood is passing. These conditions also determine the intensity of the murmur; so that, if the heart be weak, there must be considerable stenosis to produce a bruit; if stronger, less narrowing may give a similar result. It follows, therefore, that a small amount of stenosis allows but little regurgitation, and *vice versa*. The dull systolic sound heard in many cases is due to a perversion of the normal first sound, owing to thickening of the valves and cords, etc., and depends a good deal on the strength of the cardiac contractions. The anatomical changes leading to incompetency or insufficiency, are—A. Alterations of the valves themselves, especially (a) of their free edges; thickenings, excrescences, loss of substance, adhesions, etc.; (b) of their surfaces; thickening, shortening, adhesions, etc.; B. Alterations of the apparatus regulating the movements of the auriculo-ventricular (or venous) valves, such as (a) thickening, shortening, and crumpling of the chordæ tendinæ; (b) degeneration, and especially of the fibrous kind, of the muscles attached to them (papillary muscles, columnæ carneæ), by which they lose their elasticity (? contractility—*Rep.*); C. Dilatation of the fibro-cartilaginous ring between the auricle and ventricle alone, or combined with the causes under A or B. The changes inducing stenosis of the venous channels or auriculo-ventricular openings, are (a) irregularities, excrescences, etc., which occur on the free edges of the valves towards the auricles; (b) narrowings, excrescences, etc., of the fibro-cartilaginous rings of the auriculo-ventricular openings; or (c) the causes under (a) and (b) combined. We thus see that there may be causes of murmurs apart from disease of the valves themselves. The degeneration of the carneæ columnæ consequent on myocarditis, as a cause of insufficiency of the auriculo-ventricular valves, was first pointed out by Hamernik (1843-44), then by Dittrich and others. Virchow described the pathology of the muscular changes in Bd. iv. of his *Archiv*. Botkin maintains that we may even diagnose it, and gives it the name of *muscular incompetency*. It occurs transitively in anæmia, malaria, leukæmia, and acute contagious diseases. If permanent, it results from chronic myocarditis. Incompetency from dilatation of the auriculo-ventricular orifice, first described by Gendrin, and denied by Bamberger, has been pretty well settled by Friedreich, Lebert, Perls, and Wulff. It is most common in the tricuspid valve. Therefore, in cases pointing to valvular incompetency, should the valves be healthy, we should not forget the muscles and the fibro-cartilaginous rings. Yet it is certain that there are cases in which the clinical or auscultatory signs of incompetency are all present in a typical manner, and *post mortem* none of the lesions mentioned are discoverable. Such are the cases in which the heart is twisted out of its position ("eine quere Lage annimt") by the pressure of greatly enlarged organs (liver, spleen); the pressure on the heart determines a murmur, just as pressure does on an artery when superficial. Simultaneously the lesser circulation is embarrassed, the second sound is intensified over the pulmonary artery—in fact, all the signs of incompetency are present. Such murmurs are functional or inorganic, since no disease of structure is discoverable *post mortem*. [To these

should be added for completeness, the cases in which the heart or great vessels are twisted and dragged up on to one side by contraction of the lung, or by effusions into the pleural cavity.—*Rep.*] But the cases remain in which there is valvular incompetency, as proved by *post mortem* examination, and no murmur, not even the ghost (Surrogat) of one, can be heard. Forty-four years ago Hope described such cases. More recently Stokes, Buchner, Dieulafoy, etc., have done the same. There are cases, also, affecting the arteries only, which need not engage our attention. It has been said before that, in cases of great incompetency, there may be no bruit even with a swift current of blood. When, therefore, other signs of incompetency are present, and we get no bruit when the heart acts well and quickly, we may conclude that the chink permanently open is a wide one. With weak hearts, the difficulty is still greater. In this way digitalis sometimes helps one to a diagnosis, by rendering the heart's contractions more moderate. We must remember, too, that diastolic bruits are often not heard when there is stenosis of the ostium. Again, nearly all stenoses are coupled with a certain amount of incompetency. The auricles are usually less vigorous than the ventricles, and hence one source of failure in hearing diastolic murmurs. Thus the absence of signs of slight stenosis may be explicable by a large amount of incompetency. The existing chink may be widened by fresh endocarditis or myocarditis; or, in cases of fatty and other degenerations of the heart, the blood stream itself may do it. The following conclusions seem fairly drawn from the above statements.

I. There are cases presenting the physical signs, or clinical picture of incompetency of the auriculo-ventricular openings, in which the *post mortem* examination shows the valves to be intact; but the diagnosis may be considered justified if either (a) a muscular, or (b) a relative, incompetency be demonstrable; and further if the pressure of an enlarged solid organ be proved to have been present. But

II. There are cases wanting the physical signs, and thus the clinical picture is imperfect, in which *post mortem* examination reveals considerable changes in the valves or their regulating apparatus. These are long-standing cases of valvular disease, in which the interval between the incompetent valves is a wide one, and in which also the force of the heart is greatly lessened by endocardial, myocardial, and pericardial diseases or metamorphoses. Thus there is no direct proportion between the loudness of the murmur and the amount of valvular mischief.

[The reporter has but slightly abridged the above, because the subject is of great interest at the present moment; for there is a growing scepticism on the subject both of cardiac and pulmonary auscultation, probably due to the rash interpretation of physical signs or of their absence.—*Rep.*]

KLINGELHOEFFER ON EPIDEMIC JAUNDICE.—Dr. Klingelhoef, of Heusenstamm near Offenbach on the Main, writes as follows in no. 6 of the *Berliner Klinische Wochenschrift* for 1876 (February 7). Very few epidemics of jaundice have been observed, and very few recorded. The epidemic to which attention is now drawn was not so remarkable for intensity, as for its great extent, and for the long time it lasted. Most of the cases occurred in the place where the writer resides, only a few in the neighbourhood. Heusenstamm has from 1,300 to 1,400 inhabitants. Of these only the middle-aged were

attacked; no one under twenty suffered from it. Thirty-five cases were treated by Dr. Klingelhoeffer, but some others were sufferers at the same time. The first case occurred on October 10, 1874, the last on March 24, 1875, so that the epidemic lasted about six months. Both sexes were affected in about the same proportion. All these cases of jaundice were of a catarrhal nature, and all were complicated more or less with catarrh of the stomach. Gastric catarrh is rather common amongst this population, which is chiefly composed of factory-workers, but their attacks generally occur in the summer months. Up to this time there was no general prevalence of this complaint in the autumn and winter months. Jaundice was rare, and months often elapsed without any case of jaundice occurring, except as a secondary complication in other diseases. But, late this autumn and winter, there were a great many cases of gastric catarrh, and nearly all of them were complicated with jaundice. Dr. Klingelhoeffer says that he himself, though by no means a likely subject, suffered from a teasing gastric catarrh, although without any jaundice. No cause can be assigned for the prevalence of gastric catarrh at this time, except the epidemic influence (*Genius epidemicus*). The gastric catarrh usually preceded the jaundice by a few days; in a few cases, however, the jaundice was the first symptom which attracted the patient's attention. There was nothing very peculiar about the jaundice, but all the patients complained of extraordinary feelings of weariness and muscular depression even in the beginning of their malady, before the jaundice was noticeable; indeed the case could often be diagnosed from this symptom. This early prostration is contrary to the opinion of Niemeyer, who considered the loss of power and slowness of the pulse to be a consequence of disturbed digestion, especially of altered absorption of the fat. The patients seldom complained of headache, but almost invariably complained of giddiness. In no case could yellow vision be established. The irritation of the skin was not in proportion to the amount of jaundice. When there was only a slight deposit of bile-pigment in the rete Malpighii, the itching was often very tormenting. In other cases of intense coloration, the itching was entirely absent. The general course of the disease was very mild, with the exception of a few cases to be mentioned presently. A large number of those attacked were not obliged to keep their beds. In the majority of the cases perfect recovery ensued in a few days. The effect of the jaundice on pregnancy, and the severity of the attacks in pregnant and lying-in women, are interesting points; since dangerous symptoms only occurred in these, and premature delivery happened in several cases. The facts are briefly as follows.

Mrs. B. W. suffered from jaundice a few days before delivery, but had no medical advice. She went her full time. On the second day after delivery, Dr. Klingelhoeffer found her deeply jaundiced, and in a state of delirium alternated with sopor and coma; symptoms which could only be attributed to the jaundice, by exclusion of other kinds of disease. She recovered after some days, during which the prognosis was gloomy. The child was put to the breast, even whilst the mother was unconscious; it was never jaundiced, and did well.

Mrs. J. R. was attacked with jaundice in the seventh month of pregnancy; after some days she had wild delirium, alternating with sopor and coma. The child was prematurely born; it lived a few days,

but never took the breast, and died of asthenia. The mother recovered.

Mrs. F. W. became jaundiced in the seventh month of gestation. Premature delivery occurred; the child lived, was jaundiced, and very fretful for want of breast-milk (like all her children), but did well. The mother was intensely jaundiced, but had no very dangerous symptoms. She recovered after a few days.

Mrs. R. B. attacked with jaundice like the other in the seventh month. Premature labour set in, and was completed artificially. The child was not jaundiced, but could not suck, and died exhausted after a few days. The mother soon recovered.

Mrs. Ch. H. had jaundice in the eighth month of pregnancy, with threatening cerebral symptoms; after a few days she had delirium, sopor, and coma; labour set in when she was moribund, and she died in the very act of giving birth to a dead child.

The treatment of these cases was chiefly directed to the gastric catarrh, and principally consisted in regulating the diet, and in the administration of carbonated alkaline and Carlsbad salts, either in small or purgative doses. In the more severe cases, bark and wine were given. Perhaps transfusion might have done them good.

[The reporter, in the absence of any details as to temperature, or the size of the spleen, will not draw any conclusions as to the real nature of this epidemic. It does, however, seem at first glance not unlike some epidemics of relapsing fever, or perhaps more like the 'bilious fever,' well known to many country doctors, though not admitted into our recognised nosologies.—*Rep.*]

FERRAND ON HEPATIC GLYCOGENESIS, AND ON THE USE OF ALKALIES IN DIABETES.—*La France Médicale* for 1876, p. 60, contains a critique by Dr. E. Ferrand on the recent researches of MM. Bretet and Cornillon into the action of alkalies in diabetes. The author commences with a succinct and eulogistic summary of the researches of M. Claude Bernard; as these, however, are at least as well known in this country as in France, and perhaps better appreciated, it is scarcely necessary to reproduce this part of his article. Suffice it to say that he successfully vindicates for M. Bernard the right to rank as first, or at least one of the first, of living physiologists. MM. Bretet and Cornillon agree with Dr. Pavy that alkalies arrest the transformation of glyco-genic material into sugar. There can be no doubt, says M. Ferrand, of the great use of alkaline remedies in some forms of diabetes, but how shall we explain their action? He (? Dr. Pavy) has shown already that alkalies do not destroy the sugar which pre-exists in the blood. If it be not destroyed, is it formed in less quantity in those taking alkalies? Messrs. Bretet and Cornillon think that this is the true explanation. They place a mixture of dry starch, saliva, and water in a matras, and keep it at a temperature of 40° Cent. (104° Fahr.) It is soon transformed into a saccharine solution. This experiment is a familiar one. But if bicarbonate of soda be first added to the water, the quantity of sugar found in this second experiment is as 1 to 2.40 (in equal times) of the first experiment. If caustic potash be substituted for the carbonate of soda, the results are still more striking, for only traces of sugar can be found after prolonged maceration. Experiments made with pancreatic juice have yielded similar results. It is curious to note that the action of bicarbonate of soda is far more evident

with a pig's pancreas than with that of an ox. From their experiments they derive these conclusions. 1. Alkalies hinder glycosuria by diminishing the power of diastasic fluids to form sugar—they thus keep the blood free from excess of sugar. 2. Bicarbonate of soda acts not only on saliva, but on the pancreatic juice. 3. This action is more evident with the pancreas of omnivorous animals than with that of herbivora. Dr. Pavy had previously shown that caustic potash hindered saliva from turning starch into sugar, and that bicarbonate of soda injected into the portal vein checked the transformation of glycogen into sugar in the liver. These experiments may at least explain the temporary advantage of alkaline treatment in diabetes.

W. BATHURST WOODMAN.

M'CLELLAN ON THE CAUSES OF CHOLERA.—In the *Report on the Cholera Epidemic in the United States in 1873*, prepared under the superintendence of the Surgeon-General of the United States army, the principal part of which is by Dr. Ely M'Clellan, the causes of the epidemic are summed up as follows. 1. Asiatic cholera is an infectious disease resulting from an organic poison which, gaining an entrance into the alimentary canal, acts primarily upon and destroys the intestinal epithelium. 2. The active agents in the distribution of cholera poison are the dejections of persons suffering from the disease in any of its stages; in the dejections there exists an organic matter, which at a certain stage of decomposition is capable of reproducing the disease in the human organisation to which it has gained access. 3. Cholera dejecta coming into contact with and drying upon any objects, such as articles of clothing, bedding, or furniture, will retain indefinitely their power of infection. In this manner a sure transmissibility of the cholera infection is effected, and a distant outbreak of the disease may occur by such means at great distances from the seat of the original infection. 4. The specific poison which produces the disease known as cholera originates alone in India, and by virtue of its transmissibility through the persons of infected individuals, or in the meshes of infected fabrics, the disease is carried into all quarters of the world. Cholera has never yet appeared in the Western Hemisphere until after its route of pestilential march has been commenced in the Eastern world, and its epidemic appearance upon the North American continent has been invariably preceded by the arrival of vessels infected with cholera-sick, or laden with emigrants and their property from infected districts. 5. The respiratory and digestive organs are the avenues through which individual infection is accomplished; through the atmosphere of infected localities cholera is frequently communicated to individuals; water may become contaminated with the specific poison of cholera from the atmosphere, from surface washings, from neglected sewers, cesspools, or privies, and the use of water so infected will induce an outbreak of the disease. 6. The virulence of a cholera demonstration, the contagion having been introduced into a community, is influenced by the hygienic condition of the population, and not by any geological formation on which they may reside. 7. One attack of cholera imparts to the individual no immunity from the disease in future, but the contrary seems to be established.

DE RIDDER ON THE CURE OF NERVOUS APHONIA BY INHALATION OF CHLOROFORM.—Dr. de Ridder relates, in the *Annales de la Société Médico-chirurgicale de Liège*, a case in which chloroform inhalations gave good results. The patient was a female aged twenty-eight, of good constitution, who was affected with aphonia following a cold. This aphonia, after the disappearance of all symptoms of inflammation, resisted all means adopted for its cure. As the patient was hysterical Dr. de Ridder, thinking that the aphonia was nervous, employed without success pills of assafoetida followed by a narcotico-antispasmodic mixture. He then caused the patient to inhale the vapour of chloroform for one or two minutes every hour, not so as to produce anaesthesia, but only so as to cause slight vertigo and feeling of stunning. At the end of two days, the aphonia, having yielded gradually, had entirely disappeared. Five months later, the chloroform was employed with the same success for a recurrence of the same affection in the same subject. Lastly, a year later, the same aphonia, accompanied by a spasmodic hiccough and incessant vomiting of glairy matter, followed a violent attack of hysteria. The employment of chloroform administered in the same manner was again successful. The hiccough and vomiting yielded to the employment of 'pearls' of ether.

FABRY ON THE TREATMENT OF CHOREA.—M. Fabry relates in the *Bulletin de Thérapeutique* (quoted in *Paris Médical*, March 9, 1876) some observations carried out in the service of Dr. Perroud of Lyons, on the treatment of chorea by ether spray. This therapeutic agent, employed for the first time in 1866 by Lubetski, has given good results in Dr. Perroud's hands.

Applications of ether-spray are made along the spine by some spray-producing apparatus, such as those of Richardson or Marinier. Each application lasts from four to eight minutes. At the commencement of the treatment applications should be made three times a day; afterwards the number may be reduced to two.

Ice produces the same effect as ether-spray; a piece of ice may be passed along the length of the vertebral column for five minutes at a time.

These two means have effect by their refrigerant revulsive action on the excito-motor point of the nervous centres.

THOMAS ON THE LOCAL TREATMENT OF CHRONIC DYSENTERY.—Dr. T. Gaillard Thomas (*New York Medical Journal*, January, 1876), relates the following case. The patient was a woman who had suffered for five years from chronic dysentery, following on an acute attack, which had resisted all the known or frequently used forms of treatment. During these five years acute attacks had been frequently added to the chronic malady. The smallest number of motions daily during this period was eight, and they frequently were as many as twenty-seven or more.

When Dr. Thomas began his local treatment the patient was in a 'desperate condition' of debility.

Dr. Thomas's treatment was as follows. The patient being placed in the left lateral position, under the influence of an anæsthetic, with the aid of a long duck-bill speculum and retractor, the rectum was explored as far as the sigmoid flexure. The mucous membrane being washed, it 'was seen swollen,

œdematous, hanging in hæmorrhoidal masses, and studded with deep ulcers, with greyish bottoms. It was of a deep almost violet hue. On a subsequent occasion, all the ulcers from the anus to the sigmoid flexure were lightly touched with commercial nitric acid, by means of a piece of wet cotton, on the end of a whalebone rod. But little pain was afterwards experienced; and, similar applications being made twice more at intervals of a week, the patient was cured. Rest and milk-diet were ordered during the treatment.

Dr. Thomas thinks that there is no danger of rectal stricture from the use of nitric acid, if care be taken to avoid cauterisation sufficient to produce sloughing.

W. DOUGLAS HEMMING.

FISCHER ON THE TREATMENT OF AORTIC ANEURISM BY ELECTRO-PUNCTURE.—In the *Berliner Klinische Wochenschrift*, November 8 and 15, is the account by Dr. F. Fischer, of Heidelberg, of a case of aortic aneurism, treated in that city by Dr. Friedrich by electro-puncture, after the method of Cini-selli. The case was a very unfavourable one, with very severe neuralgic pain, dyspnœa, and dysphagia, and occasional severe epileptiform seizures. The main object of the galvano-puncture seems to have been to relieve the pain. In this it entirely failed, but the first application gave much relief to the dyspnœa and permanently relieved the dysphagia. A second application, however, was perfectly unsuccessful, and the patient died shortly afterwards of dyspnœa. The main interest of the case lies in the fact that it is, as far as Dr. Fischer knows, the first published case of electro-puncture in the treatment of aortic aneurism in Germany. Otherwise, it is entirely inconclusive. The galvanism, however, seems to have produced some slight decrease in size and pulsation and consequent amelioration of some of the symptoms, and to have done no absolute harm, and is so far encouraging as a precedent.

T. HOLMES.

TENNESON ON ASPHYXIA OCCURRING DURING THORACENTESIS.—In the *Union Médicale* for February 22, is reported a paper read by Dr. Tenneson, before the Société Médicale d'Emulation, upon the above subject. M. Tenneson relates the case of a lady, aged forty, of decided hereditary tendency to phthisis, and for many years the subject of chlorosis, who on April 2 was seized with pleurisy, resulting in moderate effusion into the right pleura. She only made an imperfect recovery, and on August 5 there was evidence of a reaccumulation of fluid. Thoracentesis was performed the next day by means of the aspirator. Between 300 and 400 grammes of serous fluid had been removed when the patient, who had been restless since the commencement of the operation, became much agitated and declared she was suffocating. The face appeared natural, however, and the pulse was unaltered; and M^{de} C., being known to be very nervous, her cries did not excite uneasiness. The liquid continued to flow, but after twenty or thirty seconds the cries of the patient suddenly ceased, her face became markedly cyanosed and covered with sweat, the eyes became fixed and dull, the extremities cold, and the respiration stopped. Simultaneously the liquid still flowing became sanguineous, and air entered the receiver in large bubbles. The cannula was promptly withdrawn; the patient was roused and stimulated, wine being administered, and fresh air admitted to the room. M. Tenneson made ready to

perform venesection, when the symptoms of asphyxia rapidly amended, and in a few minutes M^{de} C. was out of danger. Six hundred grammes had been removed. There were almost natural breathing and percussion on the right side, with no œdema, râles, nor evidence of pneumo-thorax. Only a very little fluid remained in the chest. Subsequently there was a little sero-spumous expectoration. The effusion recurred to a less degree, and then became gradually absorbed, and the patient tardily recovered. In commenting upon this case, M. Tenneson observes that, unlike the cases of M^{de} Besnier and Legroux, the cause of the symptoms threatening life here was undoubtedly sudden congestion of the lung; an afflux of blood determined by the production of a partial vacuum in the chest. M. Tenneson does not doubt that the lung had become punctured in the last stage of the operation; and he refers to the possibility of such a puncture, innocent in itself, having given rise to reflex bronchial spasm, and so to an asthmatic seizure. He thinks such an hypothesis improbable, however; whereas pulmonary congestion he regards as inevitable. The tendencies of this pulmonary congestion are in practice, however, singularly varied. Most usually it escapes observation, thoracentesis being completely inoffensive. A continued fatiguing cough is the most simple of the accidents it provokes. It may happen that the congestion, insignificant during the operation, increases in succeeding hours. M. Tenneson quotes some observations of M. Lereboullet, who attributes a slight febrile attack, with impaired percussion, resonance, and moist crepitation over one side, attended with dyspnœa and sero-spumous or sanguinolent expectoration, which may occur one, two, or three days after the operation, to this cause; such symptoms usually lasting four or five days; or an attack of congestion may proceed to more extensive œdema, and rapidly asphyxiate the patient, as in cases related by M^{de} Terillon and Lionville. Finally, as in M. Tenneson's own case above related, life may be menaced by the same cause during the operation. In both slight and severe cases, albuminous expectoration is to be observed, and sometimes appears to be a salutary symptom, serving to evacuate morbid material. More rarely hæmoptysis is observed, or hæmorrhage into the lung may result from the hyperæmia. M. Legroux has related a case in which fatal pulmonary hæmorrhage occurred shortly after thoracentesis. M. Tenneson would seek for an explanation of the varied intensity, course, and consequences of this affection, whose pathogeny he regards as uniform, in some antecedent pathological condition of the lung or of the patient himself. He thinks that pulmonary congestion is to be dreaded during or after thoracentesis in those whose lungs are the seat of tubercular disease; and he thinks that sparsely scattered granulations are more dangerous in this respect than even large centres of caseous pneumonia.

M. Tenneson would neither avoid nor postpone the operation from fear of this accident, but would perform it with greater precautions. He would dispense with the aspirator, and use a fine trocar protected by gold-beater's skin and furnished with a stop-cock, so that the flow might be arrested from time to time. In the event of asphyxial symptoms presenting themselves he would adopt the usual remedies; but if they be not speedily successful, he recommends the prompt employment of venesection.

R. DOUGLAS POWELL, M.D.

KEUSSNER ON LEUKÆMIA.—In the *Berliner Klinische Wochenschrift* for February, 1876, p. 109, Dr. Keussner reports two interesting cases of leukæmia, which came under the care of Professor Naunyn of Königsberg.

The first is that of a woman aged forty-six, who had suffered from ague at the age of sixteen, and successively from cholera, typhus, and small-pox in 1866. Since these illnesses she had been strong and healthy. On July 4 she was taken with shivering, followed by fever, violent headache, and severe pains in the legs. Later she had cough, difficult micturition, and painful swelling of the right cheek. On admission, July 17, she was well-nourished, lying low in bed and drowsy, but giving intelligent answers; she complained of the swollen cheek and of headache. The skin was hot, and of pale, rather dirty tinge. There was slight œdema of the ankles, and on the legs, especially below the knee, were numerous hæmorrhagic spots, varying in size from that of a pin's head to that of a pea. Similar spots were seen on the upper extremities and abdomen, as well as larger patches of the size of a shilling, evidently situate in the deeper layers of the integuments. She had a painful œdematous swelling of the right parotid region, and some swelling of the submaxillary gland, posterior wall of the pharynx, and soft palate, while the gums and tongue were ecchymosed and covered with sordes. The abdomen was distended, soft, and tender, especially in the hepatic region; the spleen projected beyond the edge of the ribs, and its dullness reached up to the seventh rib in the axillary line; the liver was not enlarged. The urine contained traces of albumen; the pulse was 124, the evening temperature 104.9°. On the two following days she was more drowsy, frequently delirious, and passed urine and feces under her; fresh hæmorrhages occurred, and the temperature continued high. A microscopic examination of the blood on July 20 showed an undoubted leukæmic condition: the white corpuscles were considerably increased in number, were mostly very large, and contained several nuclei; the transitional corpuscles described by Klebs, Neumann, and others were also present. The patient died on the 22nd. At the inspection, ecchymoses were found in the skin, on the surfaces of the lungs, under the visceral pericardium, in the septum cordis, and in the pelvis of each kidney. The blood in the cavities of the heart was partly fluid, partly in the form of clots which, besides being soft, were remarkable for their dirty red-brown chocolate colour. The spleen was enlarged, measuring eight inches in length, four in greatest breadth, and two in thickness at the hilus; its tissue was moderately resistant, brownish red on section, and yielded a greasy pulp; the follicles were not distinct. The kidneys were pale, the liver somewhat enlarged, with distinct lobular markings. The intestines were normal. The medulla of the ribs and humerus was converted into a greenish yellow puriform material of almost diffuent consistence, which, placed on a glass surface, diffused itself like a drop of tenacious fluid, just as has been described to be the case in leukæmia by Neumann, Ponfick, and Mosler. After a time the change of colour described by Neumann took place, the surface assuming a greyish red appearance.

The case was at first regarded as one of typhus complicated with scorbutus; but the condition of the blood and of the medulla of the bones found after death proved that it was an example of genuine

leukæmia. Its origin and course, and especially its acute development, stamp it as a peculiar variety of the disease.

Dr. Keussner's second case is that of a man, aged thirty-eight, who in the winter preceding admission suffered from pains in the left side, shortness of breath, and dry cough. In the autumn of 1874 he observed a hard tumour on the left side under the ribs, which was tender to the touch, and with each attack of pain became larger and harder. Headaches, pain in the joints, depression, and general malaise followed, and he was admitted November 2, 1874. The spleen was found enlarged, extending nearly to the anterior iliac spine; its dullness reaching above to the sixth rib in the axillary line. The liver did not project beyond the edges of the ribs; the urine deposited an abundant sediment of lithates, but contained no albumen. Microscopic examination of the blood showed a very considerable increase of the white blood-corpuscles, the proportion of which to the red corpuscles was as 1:2 or as 2:3. Transitional forms were also found. On November 4, he suffered from vomiting and painful micturition; the abdomen was excessively tender, and presented an area of dullness bounded by a horizontal line, above which the note was loudly tympanitic. Temperature, 101°; pulse, 100. These symptoms were thought to be due to peritonitis caused by rupture of an abscess in the spleen. On November 7 he died, the line of dullness having risen by that time about three finger-breadths. On inspection, the abdominal symptoms were found to be due to an enormous quantity of blood, which had been effused to the extent of several litres, behind and among the muscles of the abdomen, and was separated from the cavity of the abdomen by the parietal layer of the peritoneum. The spleen measured eleven and a half inches in length, seven in breadth, and four and a half in thickness. It was moderately firm, pale red, with small yellow points on section, and presented at its upper end a small, wedge-shaped, sharply limited, dark red mass. The tissue of the liver had an icteric tinge, and the lobular markings were distinct. The medulla of the ribs and humerus was of the same consistence as in the preceding case.

CHVOSTEK ON THROMBOSIS AND EMBOLISM OF THE ABDOMINAL AORTA.—In the *Allg. Wiener Med. Zeitung*, for January and February, Dr. Chvostek gives a detailed account of a case of thrombosis of the abdominal aorta, and adds a summary of all the similar cases he has been able to find on record.

A soldier, aged twenty-one, had suffered a few days from shortness of breath, when he was taken at ten o'clock at night, while in bed, with a violent pain in the right lower extremity, and an hour afterwards with similar pains in the left leg and in the abdomen. The pains soon ceased in the abdomen, but persisted in the lower extremities. Formication and diminished mobility were then noticed, the limbs became pale and cold as if dead, and gradually swelled. On the following morning at 10.30, the patient felt weak, and had moderate elevation of temperature. The heart's impulse was in the fourth space, præcordial dullness not increased, the first sound somewhat prolonged, and the second accentuated. Nothing abnormal was observed about the vertebral column. The abdomen was rather prominent and tense, and everywhere tender on deep pressure. Both legs were swollen from the knee downwards, and presented

a bluish or blackish-red colour from hæmorrhagic effusion, which extended from the toes on the right side to the lower third, on the left to the upper fourth of the leg. Below the left inner malleolus was a large blood-coloured blister, and smaller ones elsewhere. There were violent pains in the affected parts, when the soles of the feet were pressed upon, and the movement in the ankles and toe-joints was very slight, though the knees could be moved more freely. Both femoral arteries were distinctly smaller, and their beat feebler, than normal, and a systolic murmur was audible in each. Pulse, 76. In the evening the temperature was 103° F. On the following day the bullæ were larger, and fresh blisters and ecchymoses had appeared: the patient however felt better, sensation was improved, and the femoral pulse was stronger. During the next fortnight, the swelling diminished, the bullæ shrivelled, and the effused blood underwent the usual changes of colour, but some sloughs formed at the bases of the bullæ and the inguinal glands enlarged.

On the seventeenth day of his illness, he was only just able to walk a few steps, supported by two persons, and fresh hæmorrhages occurred in consequence. On the twentieth day, he was much emaciated, weak, and passed feces involuntarily. On this day the abdominal aorta was found somewhat wider than normal, and strongly pulsating from the epigastrium to one inch above the navel, but from that point downwards its pulsation was weaker even than that of the femorals. On the thirty-ninth day there was still some hard œdema of the lower parts of the legs and of the feet, with recent ecchymosis of the right leg; the patient was too feeble to walk, but could move the legs freely in bed; they readily became livid and swollen, if allowed to hang down. Two months from the commencement of his illness he was still unable to walk more than a few steps with the aid of crutches. The legs were wasted, brown in colour, somewhat infiltrated at the lower parts, and presenting pigmented scars resulting from the sloughing above mentioned. No pulsation could be felt in the aorta below a point one inch above the navel. On examining the spine, the second and third lumbar vertebræ were found projecting backwards, and their spinous and transverse processes apparently much enlarged, so as to give to these vertebræ a width of five inches, and much resemblance to a tumour.

The author, in discussing the case, points to the absence of pulsation in the lower part of the aorta, as indicating complete obstruction, or extreme contraction of the canal of that vessel. In favour of the view that it was not completely obstructed, it is to be observed that even after 2½ months there was no collateral circulation, that ten hours after the occurrence of the symptoms there was pulsation, though very faint, in the femoral arteries, and lastly, that only a very small extent of the surface was affected with gangrene. The suddenness of the symptoms points to embolism; and though the two limbs were not affected at precisely the same moment, it is improbable that the two iliacs were separately blocked, since, according to experience, embola reaching the iliac arteries usually obstruct them completely, and lead to more or less extensive sloughing. The origin of the embolon was at first assumed to be cardiac, but after the discovery of the condition of the lumbar vertebræ, it appeared likely that their enlargement, probably malignant, had led to disease of the aorta, and consequent thrombosis, and that then the thrombus, which had formed slowly, and without

symptoms, was detached, and thus produced embolism at the point of bifurcation of the vessel.

Chvostek divides the recorded cases of embolism and thrombosis of the aorta into four groups, in each of which only a few cases are to be found—(1) Embolism of the orifice of the aorta (Cohn, Reid); (2) Thrombosis in the course of the vessel (Trost, Buhl, Tewat, Carville); (3) Thrombosis of the lowest portion (Psillander, Lallemand, Duncan); and (4) Embolism at the bifurcation (Hjelt, Tutschek, six cases collected by Lebert, and others by François, Virchow, etc.). The five cases of embolism analysed by the author resulted from the formation of clot in the left side of the heart, mostly in the ventricle, from perforating carcinoma, or abscess, or dilatation of the cavity. Thrombosis was caused by atheroma of the vessel in four cases, and by the pressure of carcinoma of the stomach in a fifth.

The symptoms of embolism of the abdominal aorta are the following. Immediately after the obstruction there are violent neuralgic pains in the lower extremities and hypogastric region, which persist usually for some time. There may be at first hyperæsthesia, but generally formication, paræsthesia, and often complete anæsthesia successively appear. The arteries of the lower extremities are pulseless and the limbs cold, or there may be a feeble and retarded pulse in cases of less complete obstruction or where a collateral circulation has been established. More or less paralysis soon occurs, but mostly the anæsthesia is more marked than the motor paralysis. In proportion to the completeness of the obstruction and the absence of a collateral circulation, there is more or less extensive gangrene, beginning usually at the toes and rapidly extending upwards; while œdema and sphacelus may occur as the result of compression or thrombosis of the vena cava or iliac veins. These symptoms are soon followed by general reaction; fever, sometimes with rigors, sleeplessness, emaciation, and finally delirium, collapse and coma. The cases are mostly fatal sooner or later, but cases of more or less complete recovery with the establishment of a collateral circulation are recorded by Duchek, Power, and Gull. Treatment is almost powerless, but perfect rest is enjoined, and violent local reaction may be combated by the application of cold, or abstraction of blood from the part.

F. TAYLOR, M.D.

QUINCKE ON CHYLOUS OR FATTY EFFUSIONS IN THE PLEURA OR PERITONEUM. — Professor Quincke has published (*Deutsches Archiv für Klin. Med.* vol. xiii.) three cases of effusion into the cavity of the pleura and peritoneum. These are interesting from the nature of the fluid effused, which was so rich in fatty matters as to assume quite a milky appearance.

His first case was that of a man, aged fifty, admitted into hospital for pleural effusion on the right side, consecutive on a lesion caused by the passage of a cab over his body. The fluid withdrawn by puncture on two occasions, and that shortly afterwards found on *post mortem* examination, presented the characteristics of milk or chyle, as it may be observed in animals. Microscopic examination revealed the presence of numerous minute fat-globules, and chemical analysis showed fatty matters slightly in excess of 0.01 per cent. The character of the effusion necessitated the supposition that some large lymphatic vessel, or the thoracic duct, had been

ruptured; but the *post mortem* examination did not actually establish this very plausible theory.

In a second case, a fluid similar to the preceding, but much richer in fatty matter (1.68 per cent.), was evacuated by puncture from a dropsical effusion. The cause of this extravasation of chyle must probably be looked for in the resistance offered by numerous old-standing peritoneal adhesions to the passage of this fluid through a certain number of the minute chyliferous vessels, and to consequent rupture of the capillaries, the whole network of which was enormously dilated.

Examples similar to the above are rare. Dr. Quincke cites ten from various authors. In three of the cases the effusions were pleural; in the other seven the milk-like fluid had collected in the peritoneal cavity. In a small number of the necropsies rupture of the thoracic duct, or of a large lymphatic vessel, could be verified; in others only compression and dilatation were found.

Under this head of adipose or fatty dropsy a third case is reported, in which the presence of a milk-like ascitic fluid is mentioned; but here the fatty matter, instead of being in a state of emulsion, was in the form of true granular masses, which were clearly the results of degeneration in an old-standing peritoneal cancer. Analogous cases have been placed on record by Friedreich, by Klebs (*Handb. der Path. Anat.*, p. 322), and by Lucke (*Virchow's Archiv*, 1869). Professor Quincke's case is interesting from another point of view, viz. the development of a cancerous nodule in the subcutaneous cellular tissue, at the spot where puncture had been made to evacuate the dropsical fluid.

LITTON FORBES, M.D.

BROCA ON CYSTICERCUS COEXISTING WITH TÆNIA.—At a recent meeting of the *Société de Chirurgie*, as reported in *La France Médicale* for February 23, M. Broca communicated a remarkable case of multiple cysticercus occupying the muscles and viscera, and probably also the nervous centres, the 'host' being at the same time infested by an armed tapeworm (*tania solium*). The patient, a coachman, aged twenty-seven, four years ago passed some joints of tænia, and after a while he lost consciousness and fell from his horse. This was a severe attack, which was twice renewed some months subsequently. Seven months ago he perceived the development of a small tumour on his chest, and soon afterwards a large number of similar growths appeared all over the surface of his body. He was placed under M. Broca's care for these tumours, none of which, however, appeared either upon or within the muscular substance of the tongue. These tumours, measuring from 0.4 to 0.6 inch long and 0.24 inch broad, were elliptical, indolent, situated between the superficial layers of the muscles, and had their long diameter directed towards the axis of the fibres. During his stay in the hospital, the patient passed several segments of *tania solium*. He had another attack, with loss of consciousness, but without epileptiform seizures. The left eye also underwent a slight alteration of vision, but no important lesion of the retina was observed. From the patient's statement, and from the nature of the growths, M. Broca easily made a diagnosis, which was confirmed by microscopic examination of one of the enucleated tumours. The treatment consisted in tapping all the tumours with a fine cataract-needle. M. Broca thus performed nearly 400 of these tapplings, which

resulted in the slow disappearance of the tumours in about a month. The final transformation of the cysticercus thus tapped is that to which M. Lancereaux has given the name of barley-grain conversion. When the fingers are passed over the muscles where the cysticerci have been treated by tapping, the sensation of grains of barley is thus communicated. The report states that this is the first case in which the co-existence of tapeworm and cysticerci has been observed in the human subject.

T. S. COBBOLD, M.D.

FLINT ON PNEUMOTHORAX.—Dr. Austin Flint, sen., in Seguin's series of American *Clinical Lectures*, discusses the various conditions which may give rise to pneumothorax, and concludes that, excluding the rare instances of causation by a hydatid cyst situated in the lung bursting into the pleura, and the rupture of that membrane by blood extravasated beneath it, it is dependent on four conditions.

1. Empyema. Pus accumulating in the pleura will sooner or later make its way either through the walls of the chest or the lung, and sometimes in both directions. Perforation of the lung is generally denoted by sudden expectoration of pus, and in some cases the quantity is such as to destroy life suddenly by suffocation. In one case of Dr. Flint's complete evacuation of the pleura took place, and recovery occurred; but, as a rule, if expectoration be alone relied on for the removal of the pus, the patient sinks from prolonged emaciation and exhaustion. Two instructive instances of empyema are given, of empyema causing pneumothorax, and of the great advantages of free incisions and carbolic acid injections. In both, great gain of weight followed.

2. Pneumothorax from interstitial empyema. Of this rare form, Dr. Flint gives an interesting instance in a pedlar, aged twenty-nine, who was seized while carrying his pack with sharp pain in the side, which disappeared, but was followed by marked dyspnoea, precluding all active exercise. The left chest was dilated and tympanitic, and the heart dislocated to the right of the sternum. Amphoric sounds and metallic tinkling were audible, and vesicular murmur was absent. There was no evidence of fluid. In less than a month all signs of pneumothorax had disappeared, the heart returned to its normal position, and the vesicular murmur was everywhere audible. The patient, on resuming his occupation, had a return of the symptoms, which disappeared as before; and eleven months later he was reported as being quite well, but as having relinquished his old profession.

3. Pneumothorax in circumscribed gangrene of the lung. Here the gangrenous mass is situated near the superficies of the lung, and, being devoid of pleuritic adhesions, sloughs off into the cavity of the pleura—an exceedingly rare form of the disease.

4. Pneumothorax in phthisis. Dr. Flint states that in his 700 tabulated cases of consumption pneumothorax occurred in 24, or $3\frac{1}{2}$ per cent., and that the perforation was always followed by effusion, occasionally purulent, and often becoming foetid. Effusion was often so rapid as to fill the chest and expel the accumulated air, to compress the lung into a solid mass, and to convert the case into what was apparently one of pleurisy or empyema.

Allusion is made to the danger of sudden removal of the fluid in these cases, as the perforation may

re-open, or rather cavities may burst into the pleura, through the too rapid expansion of the lung. If the aspirator be employed, there is some danger of the lung being wounded by the needle. The author advocates, in such cases, the removal of enough fluid to relieve the dyspnoea, leaving sufficient to secure the possible advantage of compression. In all cases of pneumothorax where the dyspnoea is great, he recommends a free opening into the chest, as is done in empyema; and two instances are cited where great relief followed, the patients nevertheless dying in eleven and twelve days respectively after the operation. The author thinks that, where the tubercular disease is limited and the pneumothorax caused by the bursting of a small abscess into the pleura, free incision might prove a curative measure. The duration of life after the occurrence of pneumothorax varies, but ten months was the longest period reached by any of Dr. Flint's twenty-four cases, after perforation had taken place. In circumscribed pneumothorax, on the other hand, where the effusion of air is limited by adhesions, a more hopeful prognosis can be given, and an instance of complete recovery is recorded.

SURGERY.

GUSSENBAUER ON ŒSOPHAGOTOMY.—Dr. Carl Gussenbauer of Vienna reports (*Deutsche Medicinische Wochenschrift*, no. 2, 1876) a case from the hospital practice of Professor Billroth, in which, after the retraction of a large foreign body from the gullet by œsophagotomy, the patient quickly succumbed in consequence of acute softening of tubercle previously diffused throughout both lungs. This case presents many points of interest. The patient, previously in bad health, had allowed a large clasp-knife, half-opened so that the blade was at right angles to the handle, to pass into his pharynx. This large foreign body subsequently slipped down into the gullet, without causing any severe lesion to the surrounding structures. There were great difficulties attending the operation for the extraction of the knife, and the treatment of the large wound in the neck was complicated in consequence of certain symptoms due to the rapid softening of the pulmonary tubercle, the differential diagnosis of which condition was not very easy. The subject of the case was a consumptive man, thirty-four years of age, who on the morning of May 26, 1875, whilst scraping his tongue with a large pocket-knife, allowed this instrument, as he stated, to pass to the back of the mouth and into the throat during a sudden and severe attack of coughing. Attempts were made by the patient himself and afterwards by a medical man to extract this body, but without success. In the evening the patient was seen by Professor Bryk, of Cracow, who could feel on the front surface of the neck a hard and firmly impacted body just below the hyoid bone, and could with his index finger passed by the mouth touch the blade of the knife, which crossed from the anterior to the posterior walls of the pharynx on the left side, with its edge directed downwards. The lower portion of the neck was slightly swollen; the submaxillary region was not swollen. Respiration was not disturbed; the patient's voice was a little more rough than usual. Deglutition was not much impaired and the patient could drink off water from a large glass, not all at once, but still without feeling pain and without any apparent difficulty. Dr. Bryk made several forcible attempts to remove the knife by the mouth, but did not succeed. He then endeavoured to attain his object by performing subhyoid pharyngotomy, but in the course of the operation the knife suddenly passed down into the œsophagus, probably through reflex contractions of the pharyngeal muscles, which during the operative proceedings were very strong.

On the following day the patient travelled to Vienna, and put himself under the care of Dr. Billroth. The neck was then much distended through emphysema, and the skin congested. Œsophagotomy was performed at once. The operation was attended with much difficulty, and the knife could not be extracted until after extensive incision of the gullet. It was found to be placed obliquely in the canal, with the angle formed by the blade and handle directed upwards and to the right side, the blade obliquely to the left side, and the handle downwards and to the right side. The confined space, the assumed ignorance of the patient as to the size and position of the knife, and the necessary precautions taken to avoid wounding any of the large cervical vessels, caused the operation to be a long and difficult one. The patient felt much relieved after the extraction of the knife, and

M. BERTHELOT, the well-known French chemist, has been appointed Inspector of Public Instruction, in place of M. Balard.

insisted on leaving the hospital. He was re-admitted three days later, as he was very feverish, and the wounds on the neck were much inflamed. The fever persisted, and on June 2 commenced a profuse expectoration and discharge through the cervical wound of pus from the lungs. The patient died on June 6, ten days after the operation. At the necropsy there was found to be extensive infiltration of both lungs. In the upper lobe of the left lung were three large cavities filled with semi-fluid degenerated tubercle. This left upper lobe also presented signs of lobular pneumonia and gangrene. Both lungs presented all the *post mortem* phenomena of suppurative bronchitis.

Dr. Gussenbauer directs attention to two points of special interest which were observed in the progress of this case after the operation, one point relating to deglutition, the other to expectoration. Notwithstanding a very long incision through the coats of the œsophagus, and a considerable loss of substance of these coats due to gangrene, caused probably by the pressure of the handle of the knife, so that there was a large open wound passing directly into the pharynx and œsophagus, deglutition was but slightly impaired. The patient, when the wound had been plugged, could pass fluid in large quantities into the stomach, and did not complain of uneasiness in the neck when he drank off, as he frequently did, a whole glassful of milk. This clinical fact proves, as Dr. Gussenbauer points out, that the gullet plays in deglutition scarcely more than the part of an extensible tube, and that the œsophageal muscles have but very subordinate importance in the functions of nutrition. On the sixth day after the operation there was an intermittent discharge from the wound of fetid pus, concerning the source of which there were several suppositions. The simplest explanation was that of expectoration from the lung, due to advanced phthisis, as it could be clearly made out by percussion and auscultation that there were in the left lung cavities sufficiently large to supply a large quantity of purulent fluid. The fact, however, that at each discharge a large quantity of pus was poured out in a gush, and without coughing, led to the supposition that this pus came not from the lungs, but from a large cervical abscess communicating with the air-passages by means of an orifice caused indirectly by the pressure of the handle of the knife. This view was proved by the result of the necropsy to have been wrong. No perforation either of the larynx or trachea had taken place, and there was no collection of pus either in the neck or in the anterior mediastinum. This case has further interest, in showing with how much rapidity acute suppuration and sloughing of lung-tissue infiltrated with tubercle may follow a severe surgical operation.

W. JOHNSON SMITH.

SHAPLEIGH AND HAMILTON ON SOME PECULIAR CASES OF DISLOCATED HUMERUS.—In the discussion on a paper on the mechanism of the shoulder joint, read by Dr. Allis before the Philadelphia County Medical Society (*Philadelphia Medical Times*, December 11, 1875), the following case was related by Dr. E. B. Shapleigh. Being called to attend an old lady with her shoulder out of joint, he discovered that there was an axillary dislocation, with the head of the humerus resting upon the ribs, but that the glenoid cavity was filled with a mass which prevented reduction by the ordinary methods. This was found to be a large fatty tumour, which,

from its former position immediately behind the axilla, had slipped forward, and now occupied the place where he wished to put the head of the humerus. The assistance of Dr. J. W. Millick was fortunately obtained, who made strong traction upon the arm in a direction upward and outward, while Dr. Shapleigh forced the tumour backward, thus giving the bone an opportunity of slipping into place, and the reduction was readily accomplished.

Dr. G. Hamilton mentioned two cases of dislocation at the shoulder of rather exceptional features. A large and muscular gentleman fell headlong from top to bottom of a long, straight, and rather steep stairway, with such force as to drive the head of the humerus to a great distance from the articulation into the axilla. After several efforts, the bone was restored, audibly and sensibly, to its natural position, by means of the heel in the axilla, and the aid, in traction, of two men. The elbow, however, could not be brought within a considerable distance of the body. This fact, in connection with a most inordinate tumefaction of the shoulder, occurring in a very few minutes after the fall, induced Dr. Hamilton to call in Dr. G. W. Norris, who desired that his colleague, Dr. E. Peace, should see the patient. The consultation resulted in the conclusion that the head of the bone was prevented from coming into perfect contact with the glenoid cavity by some portion of muscular or other fibre, and that unusual extravasation of blood, from great laceration, was the cause of the extraordinary tumefaction. The ensuing discoloration of the integument involved the shoulder, the arm, and ulnar surface of the fore-arm to the fingers, the side of the body down to the ilium, and extended across the back to the opposite side. It did not disappear for many weeks. No permanent inconvenience in using the arm ensued.

In the second case the reduction was effected, as in the former, by placing a heel in the axilla. The patient, after reposing on the floor for about half an hour, in order to recover from the sickness and exhaustion of venesection and tartar-emetic, rendered necessary from previous fruitless efforts at reduction, was raised upon his seat, when it was at once manifest that the head of the humerus did not occupy the glenoid cavity. The arm was then placed in a sling, and the father of the young man directed to take him to the Pennsylvania Hospital in a day or two, if there were inability to use the limb. This, however, did not occur; and though not thought of at the moment, the fatigue of the muscles, from protracted efforts at reduction, and more especially the prostration of vital force from loss of blood and from the use of tartar-emetic, were, doubtless, the efficient agents in permitting the mere weight of the arm to drag the head of the bone temporarily from the glenoid surface of the scapula.

BUCHANAN ON DEPOSITION OF THE OVA OF THE FLY IN THE NASAL FOSSÆ.—Dr. W. F. Buchanan, captain and assistant-surgeon, U.S.A., relates (*Philadelphia Medical Times*, October 30) that on September 14 he was sent for to visit a Mexican woman, aged about eighty. Her son stated that two nights previously a fly had got into her nose whilst she was sleeping, and that she had now worms in her nose. She complained of pain in the nostrils, forehead, and throat, difficulty of swallowing; there was some tumefaction of the eyelids. The pulse was about 100, the bowels constipated. Her nose had been bleeding considerably, and there was a constant

sero-sanguinolent discharge. No worms could be seen; and, although her son said that he had seen them up her nose, it was thought that the symptoms might be due to other causes. A purgative of sulphate of magnesia and calcined magnesia was ordered, a small blister applied over each maxillary sinus, and a mixture of sulphate of zinc, acetate of lead, and tincture of opium injected into the nostrils. Next day, two grains of quinine were given every three hours. On September 16 the symptoms were still severe. Several maggots had appeared at the anterior nares, and one or two had been removed. The quinine was continued, sweet spirit of nitre was given, and an injection in the nares of diluted liquor sodæ chlorinatæ ordered to be used frequently. On September 17 a small orifice was noticed in the soft palate in the median line, at its junction with the hard palate, through which one or two maggots were protruding; these were removed. Twelve or fifteen had been discharged since the previous visit. Injection through this orifice and the anterior nares, etc., was continued. On the 18th the patient's suffering was great, with both moral and physical pain and continuance of occasional delirium; the opening in the soft palate was enlarged. An opening had now been caused by the maggots on the bridge of the nose at the junction of the cartilage with the nasal bone, through which, and the opening in the soft palate, about twenty-five maggots had been discharged since the previous day. The medicines were continued. A thorough injection was made through the orifices in the nose and the soft palate, and through the anterior nares, of a solution of ʒjss of carbolic acid in ʒvj of water, followed by the use of sweet oil, with directions to continue the use, in the interim of the visits, of the liquor sodæ chlorinatæ. On the 19th the patient was somewhat improved. Two hundred and twenty maggots had been discharged since the previous day. Most of them were of the size of a small goose-quill, and from five to eight lines in length. From this time the patient rapidly recovered, twenty to thirty maggots being discharged each day for a few days, when they ceased. A portion of the anterior part of the soft palate sloughed out, but, at the time of the report, appeared to be closing, as also did the orifice on the bridge of the nose. The swelling of the eyelids, pains in the head, face, and neck, difficulty of deglutition, etc., all gradually subsided until recovery. There were in all about three hundred and twenty-five maggots discharged.

HEWSON ON BONWILL'S METHOD OF INDUCING ANÆSTHESIA.—The following is an extract from an introductory clinical lecture delivered at the Pennsylvania Hospital by Dr. Addinell Hewson, and reported (with further notes) by Dr. T. H. Bradford in the *Philadelphia Medical Times* for March 4.

The use of ether, chloroform, and the like, has disarmed surgery of the greatest of its terrors; but such measures are not to be resorted to in the embarrassments to which I am now referring. What we want here are measures to diminish emotional dread, and to allay or diminish the sensitiveness of a part, so that patients can be handled or examined with as much force as may be necessary to detect all the phenomena in their cases. In the most serious cases for manipulative examinations or procedures we have not heretofore hesitated to use ether and chloroform, but even in many of them we should feel that we were yet in want of the *desideratum*,—

some means to be used readily without rest, inconvenience, or annoyance. This, I believe, I have really to show you here to-day, in Dr. W. G. A. Bonwill's method of diminishing or allaying sensibility by rapid respirations.

You have all of you, I have no doubt, experienced the effects of rapid and deep respirations after violent running, or of blowing hard to ignite a fire—especially the confusion of sight and bewilderment of mind. These Dr. Bonwill recognised many years ago, associated with numbness of sentient nerves, as dependent on the rapidity of the respirations. Pursuing the subject, he has brought it to practical use in his profession—that of dentistry—in which he uses it constantly to diminish the sensitiveness of dentine, and even to produce such insensibility as to allow of the extraction of a molar tooth without pain. Of the latter I have had a demonstration in my own family, which has led me to the study of the subject myself, and this with the most gratifying results. I have used it in stitching wounds, in handling oversensitive parts, and in probings and the like. The surgeon's probe, the earliest of his aids in exploring his cases, is an object of special dread to his patients, and so constantly is it resorted to that even well-informed people forget or are ignorant of its purpose.

The solid metallic character of this instrument elicits, when its end is brought into contact with a hard substance, peculiar sensations, which, to an educated touch, will designate with great accuracy the character of such a substance, and its relations with the parts where it is concealed. The phenomena as regards the latter point will be very much intensified by using in addition the 'sounding-board,' devised, as you know, for increasing the value of the sounding in exploring the bladder.

The slightest contact of the probe held by this sounding-board will not only show you that the substance it is touching is hard and is free or firmly fixed, but will also give you a clear idea of the amount of its hardness, and even of its size. This, as you see, I can demonstrate to the whole of this large class by touching various articles on the table before me with the instrument so guarded. Now, I wish to make some actual demonstrations of the kind on two boys who have been sufferers for a long time with diseased bone. In both these cases I had a most gratifying demonstration of Dr. Bonwill's method a few days ago, when I first came to examine them with the probe. The first case is a bright little fellow, who looks at me very cheerfully to-day, and in this respect is very different from what he was at the beginning of our interview some days ago: he then dreaded the probing. He is a boy who has gone through a good deal of suffering. You will remember his having been before in the clinic on more than one occasion. He was admitted on January 12. A year ago he fractured his tibia in its shaft and at his malleolus, by falling downstairs. He was treated for the injuries, but in about six months an abscess formed, which was lanced. It was then found that there was extensive periostitis. The limb, after this, was constantly breaking out, and giving the child great annoyance.

On admission, the patient looked well, was well nourished; the right leg was much swollen, and red, with two fistulous tracks leading to diseased bone, and from which exuded a whitish, semi-purulent discharge. The leg was poulticed, and the patient ordered half a drachm of cod liver oil with

lacto-phosphate of lime three times a day. On January 15 he was brought before the class, and, after he was thoroughly etherised, Dr. Morton made a free incision about three inches in length down to the bone, which he found in a necrotic condition. He removed a considerable portion of this by a chisel. He then used a trephine, and bored through to the medullary canal, where he found two spicula of dead bone, which had apparently been the whole cause of the trouble. He removed these and all the rest of dead bone that was free. The wound was filled with charpie saturated with carbolised oil, and bandaged from the toes up. This same kind of dressing has been continued, with very satisfactory results. The wound is filled with healthy granulations; but there is a fistulous opening high up near the knee, and some distance from the wound, evidently communicating with dead bone. This I explored the other day with the simple probe while the patient was breathing with great rapidity, and I detected a small and free piece of dead bone, without causing him any pain. To-day I will make the exploration under the same circumstances, with a probe armed with a sounding-board.

The patient, being on the operating-table, was directed by Dr. Hewson, who was holding the board and probe in his hand, to breathe rapidly. He did so for only a few seconds, and then ceased, and directed his eyes to the instrument. He was told he was not going to be hurt.

He would not, however, continue deep inspirations anything like long enough (Dr. Hewson stated that it required fully three minutes, according to his experience). The boy then grew nervous, and began to cry, refusing to breathe at all with any exertion. The doctor then left him on the table and turned to the other case.

This was a lad sixteen years old, who had been admitted on January 25, for necrosis of the foot. Three years since, he was trampled upon by a horse, injuring the left foot. With attention and rest he soon regained the use of this foot. But three months ago the same kind of accident befell the same foot, doing it a great deal of damage. It is now much swollen, with numerous sinuses, abundant discharge, and great sensitiveness.

The probing at the time of his admission was very painful. When Dr. Hewson examined him on the 3rd instant with the probe, after he had been breathing rapidly for about five minutes, he did not evince any pain whatever. He was therefore thought to be likewise a good subject for demonstration to-day. He could not, however, be induced to breathe as was necessary.

The want of success in these two cases was evidently due to great emotional excitement, possibly from dread of the introduction of the sounding-board. The first boy had special dread of being etherised. The writer of this report then volunteered to try the process before the class. It was his first attempt, and was made sitting erect, with his right hand resting upon a table. Breathing rapidly (for about three minutes) was attended first with a tingling sensation of the surface, especially of the fingers, and a feeling as though the surface was all swelling. Then there followed a dizziness or confusion in the head, with consciousness well preserved, but with a feeling of inability to resist or act in an independent way. He remembered well being frequently asked by the doctor if he was hurting him, but had no recollection afterwards of the pin sticking him, much less of

its having been firmly imbedded in his flesh, as he found it when he had ceased the rapid respirations and the anæsthetic effect had passed off.

Some cases of interest, as showing important points in diagnosis, were after this brought before the class, and the rest of the hour was occupied in their discussion. After dismissing the class, Dr. Hewson went with the writer to the receiving ward, where they found waiting a boy who had fallen upon the ice an hour previously and had sustained a severe injury to his left wrist. He was evidently suffering, and in great dread of being hurt, and the doctor directed him at once to try the rapid respirations. This, in two minutes and a half by the watch, showed some dizziness in the boy's head—when the doctor picked up the limb and moved it about with the utmost freedom, diagnosing a bad sprain of the wrist, and the absence of fracture. When the boy was recovering he took to crying, on account, he said, of the dizziness and confusion he had experienced. He said positively he was not suffering any pain, the limb having been put in the easiest position possible.

SYPHILOGRAPHY.

DUBUC ON A RARE FORM OF SYPHILITIC INITIAL LESION.—Dr. Dubuc describes a primary syphilitic sore resembling herpes (*Annals de Dermatologie*, 1874), which has not, he thinks, hitherto been recognised as an occasional commencing form of constitutional syphilis. In the six cases adduced, the affection began as minute numerous erosions scattered over the glans, furrow, and inner surface of the prepuce, closely resembling those which are left when the vesicles of true herpes burst. They were, however, not seated on a red itching area, and, after a shorter or longer period, hardened and left, where each ulcer existed, a small elevated hard cicatrix, that in time faded away, and all trace vanished. Constitutional syphilis of a severe kind followed this affection in all cases. BERKELEY HILL.

CASPARY ON HEALTHY MOTHERS OF CHILDREN WHO HAVE CONGENITAL SYPHILIS.—As bearing on the solution of this question, Caspary (*Vierteljahresschrift für Dermatologie und Syphilis*, 1875, 4 Heft) gives the following case. The husband was infected with syphilis in 1872, and whilst he was treated by mercury, and for some time afterwards, great care was taken to protect the wife from contagion. In October, 1874, the wife became pregnant, and in March a macerated three-months' embryo was discharged. Professor Neumann believed that he found gummata in the maternal placenta. The woman made a good recovery. Her previous children had been healthy; and from the time of the husband's infection until the abortion she had been carefully watched by the author, and no symptoms of syphilis were found. He now inoculated her on the arm with the secretion of a syphilitic condyloma mixed with blood. The result was negative, and the woman was subjected to an inunction cure.

MONTI ON THE TREATMENT OF CONGENITAL SYPHILIS WITH FERRUM IODATUM SACCHARATUM.—Dr. Monti (*Fahrbuch für Kinderheilkunde*, Band ix. Heft 3) begins by observing that the treatment of congenital syphilis with any form of mercury has the disadvantages, that it increases the anæmia and exercises scarcely any influence upon relapses and sequelæ. Ferrum iodatum saccharatum was employed in the form of powder dissolved in milk, and given at feeding times. Its administration was continued until the affections of the skin and mucous membrane, the enlargement of the spleen,

and the accompanying anæmia, had all disappeared. The author arrives at the following conclusions. Children of all ages bear the drug well, and are rendered more tranquil by it. The disease products undergo retrograde metamorphosis. The duration of the disease is not so short as under mercurial treatment; in twenty cases it ranged from ten to sixty days, the average being twenty-two. The action of the drug is not sufficiently rapid to meet cases which require prompt interference, but in others it has the great advantage that the nutrition of the child steadily improves. Relapses are not prevented, but they occur later and in a milder form even under mercurial treatment. It has no influence upon sequelæ.

[The paper is valuable as a systematic report of a method of treatment, which, though not new, has scarcely received the attention it merits. Exception will be taken by many to the statement that mercury increases the anæmia in this disease; indeed, it has been shown by recent physiological researches that, in small doses, it increases the number of red corpuscles. (See LONDON MEDICAL RECORD, February, 1876.)—*Rep.*]

RALPH W. LEFTWICH, M.D.

KEYES ON SYPHILITIC AFFECTIONS OF THE BURSE.—Dr. E. L. Keyes publishes in the *American Journal of Medical Science* for April, a paper in which he gives cases of tertiary syphilitic affection of synovial bursæ occurring in his own treatment and collected from the writings of Verneuil, Moreau, and Petit, in all fourteen. Of these, however, two are excluded on account of imperfection. He sums up by remarking that it appears that secondary syphilis attacks the bursæ as a congestion, which, as in the early congestions of secondary syphilis, may be accompanied by pain, but which is indolent when it goes on to effusion.

Tertiary syphilis, when primarily affecting the bursæ, is in all cases insidious in its course, and indolent at first, never becoming painful until the integument is involved secondarily. When the integument becomes involved, some pain is to be expected, as observed in a few cases.

The bursæ occasionally fluctuate slightly, and probably always contain some fluid between their thickened walls, although palpation may not detect it. The presence or absence of an appreciable amount of fluid, however, does not affect the character of indolence, which seems to be common to tertiary bursitis (unless complicated by actual inflammation) with many other tertiary lesions.

In one-half the cases a traumatic exciting cause may be accused of calling out a local expression of disease; in the others there is no evidence of any such complicating cause. In all, the history, course, and result of treatment mark the malady as essentially syphilitic.

In the six cases where it is mentioned, the average date of appearance of the affection after chancre was (shortest $1\frac{1}{2}$, longest $8\frac{1}{2}$ years) a little over five years.

Whenever two bursæ were involved at the same time in one patient, they were symmetrical. Of the twelve cases, in eight the bursæ affected were situated about the knee; bursa in front of the patella double, three times; single, twice; bursa over tuberosity of tibia, once; bursa between insertion of semitendinosus and lateral ligament of knee, double, once; single, once. In the other four the bursa involved was in each case unilateral; once, over malleolus

once, under corn; once, in the palm of the hand; once, over the olecranon.

The average age of the patients was about thirty-five. Both sexes seem to suffer equally, but in all the females the bursæ about the knee were alone involved.

Treatment always afforded relief, which was generally very rapid and brilliant, especially at the beginning of an active course. Very speedy cure was effected in some of the cases. Mixed treatment in one of its forms, the mercury being used externally or internally with iodide of potassium in excess internally, seems to yield as good results as can be desired.

MATERIA MEDICA AND THERAPEUTICS.

HOLMES ON SOME AMERICAN MEDICINAL PLANTS.—Mr. E. M. Holmes, in the *Pharmaceutical Journal* for April 1, says:—California has lately proved a prolific source of new drugs for investigation and trial in America, and two more new medicinal plants have been lately introduced into notice from that country. Through the kindness of Professor Maisch, of Philadelphia, specimens of these have been presented to the Pharmaceutical Society's Museum, and a short notice of them may not be unwelcome to those who take an interest in the pharmacy of the sister country.

Eriodictyon Californicum, Benth.—This drug consists of the leafy tops of the plant, the leaves being stuck together by a resinous exudation which gives quite a varnished appearance to the upper surface of the leaves and to the stems, the under surface of the leaves, except the veins, being almost entirely free from this resinous substance. It is this curious character of the leaves which give rise to another name for the plant, *E. glutinosum*.

The leaves, which are leathery but brittle, are elliptic-lanceolate in outline, tapering below into a short petiole; the margins of the leaves being slightly toothed. The upper surface of the leaves is smooth and the veins are indistinct. The under surface is whitish from the presence of minute downy hairs, and the veins are prominent, the midrib forming a stout keel. Owing to the resinous coating on the veins, the under surface of the leaf has a strongly reticulated appearance. The taste of the leaves is very similar to the odour exhaled in spring by the opening buds of the well-known balsam poplar (*Populus Tacamahaca*, Mill.)

The plant yielding these leaves is an evergreen shrub, about four or five feet high, which grows abundantly in dry rocky places on the mountains of Northern Mexico and Southern and Central

California. The leaves are alternate, three to four inches long, and from half to one inch broad in the middle. The light purplish blue flowers are arranged in scorpioid cymes, the flowers themselves bearing a distant resemblance to the common lung-wort (*Pulmonaria officinalis*, L.) of our gardens. The plant belongs to the natural order Hydrophyllaceæ, a family nearly allied to the Boraginaceæ, from which it differs chiefly in the parietal placentation of the capsular fruit.

For the following remarks I am indebted to the *Pharmacist*, February, 1876, p. 34. 'The plant has long been used by the Spaniards and Indians as a specific for lung-diseases, from which it has obtained the name of "consumptive's weed." It is also known as "yerba santa," "mountain balm," and "bear's weed," from the partiality which bears show for its foliage.'

Dr. J. H. Bundy, of California, reports that he has cured some severe cases of chronic bronchitis; that he has successfully treated pneumonia with the drug, and that he has noticed a peculiar action upon the kidneys resulting from its use. The natives are said to make an aqueous decoction as a general tonic, and a decoction with whisky for chronic lung diseases. In acute coughs and colds it appears to be of little value.

Mr. H. S. Wellcome treated the leaves with strong alcohol for an hour, which dissolved all the surface resin, and left on evaporation an amber-coloured aromatic resin. On being afterwards exhausted with alcohol, the leaves yielded a dark green resin similar to the first in general character, but having a bitter taste. A subsequent aqueous infusion of the leaves which had been exhausted by alcohol yielded an intensely bitter extract. He therefore recommends the drug to be used in the form of tincture, 4 ozs. of the leaves being used to a pint of spirits of wine containing 75 per cent. of alcohol. Of this tincture the dose is 1 to 2 drachms. A syrup may be made by triturating the resin with powdered French chalk and then following the process for making spirit of tolu. The syrup thus made has an agreeable odour and taste, like that of the pine-apple.

Raíz del Indico.—This name is used by the natives of Mexico for the root of a plant growing along the Rio Grande.

The root received from Professor Maisch consists of fusiform tubercles, about 2 inches long, and nearly $\frac{3}{4}$ of an inch broad in the middle; the external surface is dark chocolate brown, and strongly wrinkled, with a few transverse ridges. The internal surface is of a rather paler brown colour with a reddish tinge, but does not usually present any marked feature. In some pieces, however, the large medullium can be distinguished from the cortical portion, which occupies only about one-fourth of the diameter of the root. The taste is very astringent.

Mr. F. G. Voelcker, who has examined the root, reports that the leaves of the plant, as grown by him, are entire, petiolate, 12 to 13 inches long by $2\frac{1}{2}$ to 3 inches wide, oblanceolate in outline, acute, glabrous, shining, juicy, and of a light green colour, and that from the stipules and the general appearance of the plant he infers that it belongs to the Polygonaceæ, although he has not seen the flowers.

This root does not appear to possess any advantage over bistort or other polygonaceous roots, but is chiefly interesting on account of the results obtained from a chemical examination of it. These results, as recorded by Mr. Voelcker, show that the root as-

simulates closely to rhubarb in composition. Thus, by treatment with ether, he obtained crystals, giving the reactions of chrysophanic acid, and by subsequent treatment with alcohol, he obtained bodies which he considers to be aporetin, phæoretin, and erythroretin. He also found oxalate and malate of calcium, starch, gum, albumen, glucose, and 23.16 per cent. of tannin.

WILSON ON THE DIET OF CHILDREN.—In his lectures on Dermatology at the Royal College of Surgeons (February, 1876), Professor Erasmus Wilson, speaking on the treatment of ringworm by diet, makes the following remarks. Adults deem it necessary to have three nutritive meals in the day, whilst the children of the same family are often put off with two, possibly because they are little; but they have in reality the germs of the future great, and have an abundant employment for their nourishment in building up a healthy structure for the coming man. If they be deprived of the wherewithal, the coming man and all that springs from him in the future will be weak and feeble, and as time wears on will develop those diseases which are known to be the consequence of a feeble constitution. How often do we find the diet of children reduced to the miserable standard of bread and butter and milk and water for breakfast; for dinner, meat and milk, and rice puddings, with water; and in the evening bread and butter and milk and water. No better method could be devised for engendering ringworm, scrofula, phthisis, and cancer. W. DOUGLAS HEMMING.

BENNETT ON HEAT IN THE TREATMENT OF CEREBRO-SPINAL MENINGITIS.—In the *Cincinnati Clinic* for March 25, Dr. J. D. Bennett, of Assumption, Illinois, says that the treatment which he found most successful in cases of cerebro-spinal meningitis was large doses of bromide of potassium repeated every hour or two, a blister over the spine, cold applications to the head, and the continued application of heat to the cutaneous surface. He regards this last of more importance than any one other thing in the treatment. His usual way of applying heat is, after the hot bath, to fill a small jug with hot water, wrap it with flannel and apply to the feet, fill some bottles and apply to the legs and hips, and keep them there as long as they afford relief, for which the patient is too glad to be much annoyed by their presence.

There is one thing which should be remembered; both the internal and external temperatures are subject to very sudden variations. These correspond with the fluctuations of the pulse, which rises or falls according as the internal temperature varies; and we have to regulate our treatment as these changes occur, gradually abating the hot applications as the pulse becomes normal.

HALL ON THE TREATMENT OF SUNSTROKE BY THE SUBCUTANEOUS ADMINISTRATION OF QUININE.—Mr. A. R. Hall, Surgeon Army Medical Department, in the *Practitioner* for March, remarks that the experience of several medical officers in India is now apparently sufficient to prove that the hypodermic injection of quinine in heat-apoplexy is the most successful method of treatment that has yet been adopted. In May 1869, Mr. Walter Kerr Waller, of Calcutta, told him that he had been very successful in treating sunstroke by doses of 20 or 30 grains of quinine given by the stomach, and advised

him to try it. A short time afterwards, Mr. Hall was called to see a driver of his battery, at Barrackpore, near Calcutta, who was a patient in hospital, and who was knocked down with heat-apoplexy about five o'clock in the afternoon. He found him completely comatose, with dilated pupils, stertorous breathing, face very much flushed, skin of body red and burning hot, pulse full and rapid. He dissolved 20 grains of quinine in 20 minims of dilute sulphuric acid, and about three ounces of water, and attempted to make him swallow it; but in vain. He therefore thought it a good opportunity for trying the hypodermic method. A solution of 5 grains of quinine in 5 minims of dilute sulphuric acid, and 50 minims of water, was put under his skin, in different places about the shoulders. Within one hour, the heat of surface had perceptibly decreased; he steadily improved during the night, was quite sensible next morning, and recovered without any bad symptoms. Surgeon J. Anderson, at present with the 'Chestnut troop' of Royal Horse Artillery, shortly afterwards, in the same hospital, treated a case with equally satisfactory results. Mr. Hall attended five cases of heat-apoplexy at Barrackpore, and employed this method, and they all recovered.

McKIE ON ASCITES TREATED WITH STRYCHNIA. In the *American Journal of the Medical Sciences* for April, Dr. McKie, of Woodlawn, South Carolina, states that a number of years ago a negro woman with ascites, who had been repeatedly tapped by another physician, came under his observation. The tapping was continued with considerable regularity every two weeks until the patient from some cause became hemiplegic. For this strychnia in increasing doses was prescribed, and persisted in until she recovered the use of her leg, the arm remaining useless. Under this treatment the dropsy disappeared and never returned, although the woman lived several years afterwards.

In February, 1872, Dr. McKie was called to a mulatto woman in whom abdominal dropsy had been suddenly developed, to such a degree as to require the use of the trocar early in the disease. After practising this mode of relief with considerable regularity, at intervals of about twelve to fourteen days, for a period of six months, strychnia was then given regularly three times a day for about seven weeks, and soon afterwards tapping once a month was found sufficient. The use of the strychnia was then abandoned, and the tapping resorted to every month as usual. Two years ago she again began the use of this drug in increasing doses as before, and continued it as the system would tolerate, about twelve weeks. In February, 1876, eleven months had elapsed since the last tapping, and she reported that the belly was not larger than it was before she was first attacked.

Whether these two cases are mere coincidents, or the effect of strychnia, Dr. McKie says, it is not attempted to decide, and the facts are mentioned that others who are inclined to do so may give it further trial.

BINZ ON THE USE OF ALCOHOL IN MEDICINE.—Professor Binz, of Bonn, in an article in the *Practitioner* for May, thus sums up his views regarding the use of alcohol in medicine. 1. Alcohol is very frequently a stimulant of transitory power; 2. In relatively large doses it can serve as a vigorous antipyretic; 3. Alcohol, given in small and oft-

repeated doses, is a food particularly adapted to cases where the stomach can take in no other 'combustible material' to supply warmth and working energy to the organism.

'While I thus share in the views which the late Dr. Anstie ably upheld in England, I do not hesitate, on the other hand, to declare, with respect to the requirements of the healthy organism, that I consider the use of alcohol in health as entirely superfluous.

'Where the digestion is healthy, and where a sufficient transfer of nutritive material takes place from the food to the blood, the human body is capable of accomplishing all the functions for which it is designed, and that without the use of spirituous drinks. But the case assumes a different aspect as soon as these two conditions fail. A physician may therefore recommend total abstinence to healthy persons in every instance, but he throws away one of the most valuable of medicines if he carries this principle of teetotalism into the sick-room.

BRENCHELEY ON THE TREATMENT OF INCONTINENCE OF URINE.—Mr. H. Brenchley (*Practitioner*, May), recommends the following formulæ, which he has found beneficial in several cases of incontinence of urine :—

R. Tinct. Ergotæ ℥x
Tinct. Ferri Perchlorid. ℥v
Spt. Chloroformi ℥v
Infus. Quassiae ad ʒj. Ter die sumend.

PSYCHOLOGY.

ASHE ON GENERAL PARALYSIS OF THE INSANE. — Dr. Ashe (*Journal of Mental Science*, April, 1876) has published an article in which he puts forward two very original ideas on the causation of general paralysis.

Briefly summed up, they may be stated to be ; (1), that general paralysis is caused by beer ; (2), that it is caused by an excess of phosphorus in the system.

Alluding to the two universally acknowledged forces operating in the production of the disease, viz., alcohol and excessive sexual indulgence, Dr. Ashe informs us that general paralysis is scarcely to be found in Ireland, though common in England and Scotland. He is of opinion that the disproportion in the frequency of the disease in the two countries must be held at once and entirely to negative the theory that its development is due to excess in the use of ardent spirits, and that he may add that it equally negatives the view that it is due to venereal excesses ; for certainly neither in the one direction nor in the other can it be asserted that the Irish peasant is more abstemious than his English neighbour. And, moreover, as regards the use of ardent spirits, anyone in Ireland could at once count up 10 per cent. of the asylum population whose insanity has been caused by the abuse of distilled liquors ; but the disease does not take the form of general paralysis.

But it appears to Dr. Ashe that there is a form of alcoholic indulgence in which the Englishman and Scotchman markedly distance the Irishman ; and this is the consumption of malt liquors, of which the Irishman uses but very little, but the Englishman and Scotchman a great deal.

Whether such a result should be regarded as due to the use of pure and unadulterated malt liquors, or is rather to be considered as the effect of some adulteration thereof (such as *coccus Indicus*) is an open question.

Dr. Ashe thinks that the remarkable absence of the disease in Ireland is quite sufficient to prove further, that even immoderate sexual indulgence is not a *vera causa* of the disease. Were it so, they would undoubtedly have their share of it in Ireland. But the presence of strong sexual proclivity during the course of the disease is undoubted, and Dr. Ashe has observed it in every instance. If, then, statistics forbid us to regard it as a cause, it is clear that we are bound to regard it as a consequence of the disease. It appears from numerous statistics that Ireland is almost entirely free from this disease, whether in public or in private asylums.

Another well known consequence in general paralysis is the marked tendency to fatty degeneration of all the tissues, as shown by *post mortem* examinations.

In seeking, therefore, the pathological cause or condition of general paralysis, we have the following indications of causation.

1. Fatty degeneration of all the tissues, the voluntary and involuntary muscles, the bones, glands, and brain alike giving evidence of this condition.

2. A considerable removal of the earthy constituents of the bones, to which, along with the above-mentioned fatty degeneration, the great tendency to fracture of the bones in this disease is due.

3. Considerable increase of sexual proclivity.

4. Epileptoid convulsions.
5. Alternations of excitement and depression.

It appears to Dr. Ashe that in the above summary we have an exact picture of the effects of an excess of phosphorus in the system.

Thus Pereira mentions its tendency to cause gangrene and convulsive affections. Its aphrodisiac properties are well known; and also its effect in causing temporary stimulation with subsequent depression of the entire nervous system. The well known caries of the jaw, which is found in the workers in phosphorus, very well illustrates its power of removing the earthy constituents of bone; it probably finds access, as Pereira suggests, to the jaws during life through carious teeth; to the bones in general paralysis it would, of course, have universal access if diffused through the blood.

Quite in accordance with this view of the pathological causation of general paralysis is the well known fact that its victims—in the better classes, at least—are generally men of more than average mental endowments; that is to say, according to the views generally adopted, men of more highly phosphorised brains than usual. It is found, Dr. Ashe believes, usually in men who have spent a life of active brain-exertion in a narrow and limited direction, men of intense application, rather than wide culture and numerous interests; and among such persons it is found after their withdrawal and retirement from the interests that have perhaps too completely engrossed them. The merchant retired from business is, perhaps, the type of this class; and the explanation of the phenomenon is, to Dr. Ashe's mind, of the following nature, viz., that during an active life of mental energy the phosphorus of the brain is oxidised, or burnt off into phosphoric acid, by volitional thought-processes; but that on retirement from business, when the intellect, not having a wide cultivation or broad range of interests, has but little to engage itself with, the phosphorus is discharged from the circulation in an unoxidised condition, and general paralysis is the result. It may be asked, how do we account for its non-appearance in the urine in the shape of excessive phosphates? Dr. Ashe replies that probably it passes off in the shape of hypophosphorous acid gas from the lungs, which is the method by which phosphorus, when taken internally, appears to be got rid of.

Dr. Ashe thinks we have got a hint as to that residuum of unexplained causation indicated by the difference of frequency of the disease in England and in Ireland. As a rule, England feeds on a more highly phosphorised diet than Ireland. Where England consumes cereals, a phosphorised diet, Ireland consumes the potato, a non-phosphorised. Hence, the sum total of the causation would stand as the product of a predisposing cause and a predisposed nervous system, in both of which elements of causation—if they be what Dr. Ashe has propounded—Ireland has the advantage of England. Dr. Ashe states that he is unable to discover, either by statistics or reflection, any other elements of causation in which the two countries differ.

H. SUTHERLAND, M.D.

CARPENTER ON FOREIGN BODIES IN THE BRAIN.

—Dr. W. B. Carpenter, attending physician to the Kansas State Prison, relates the following case in the *American Journal of Medical Sciences*, April, 1876. Thomas Waters, a prisoner in the Kansas State Peni-

tentiary, aged twenty-eight, who had been insane for some time, and who, during his imprisonment, had attempted suicide by swallowing a quantity of chloroform which produced violent emesis, was one evening in 1874 reported by the hospital nurse to have been putting 'wires and things into his head,' and was found, when visited by the surgeon, sitting quietly upon his cot, 'very polite,' and willing to have his head examined. This was accordingly done, when a small punctured wound was discovered an inch above the top of the right ear, from which was withdrawn, by means of bull-dog forceps and forcible efforts, a piece of No. 20 broom wire, four and three-fourths inches in length and perfectly straight. This wire had been retained in the brain for twenty-four hours, and produced no other inconvenience than severe headache, which disappeared within thirty minutes of its withdrawal. Four weeks later, Thomas Waters seized an awl and a wooden bucket lid, and by means of the latter drove the former through the top of his head up to the handle. No untoward consequences followed upon this daring experiment; and shortly afterwards Waters introduced another piece of wire, nearly seven inches in length, into the lateral opening in his head, causing it by repeated thrusts to transfix both hemispheres and impinge upon the skull at the opposite side. The result of this operation was that paralysis of the left leg and arm was induced, and that he was found in the morning 'lying helpless upon his mattress.' This paralysis and helplessness were, however, of short duration. In two weeks he began first to use the hand, then the foot, then the limb, and finally to walk. The brain-punctures and lacerations, indeed, seem to have had a beneficial effect upon Waters, for, after the third of them, he expressed a desire to live and get well, which he had not previously done; and live and get well he did. At times he had moments of reflective abstraction, but as a rule he was 'cheerful, conversant, and even witty.' Headaches occasionally troubled him; and these, when questioned about them, he was disposed to attribute to a needle and a nail, which he remembered having placed in his brain and which, with touching faith, he believed were working their way out. At the expiration of his term of imprisonment he was discharged, and died a week afterwards from a dose of morphia which he had taken, it is argued, to secure sleep, and not with a view to suicide, because he had persuaded the druggist from whom he bought it to give him handsome discount. A necropsy on his body was held in the presence of Dr. Carpenter and of Dr. Charles C. Stroyer, when, in the medullary substance of the middle lobe of the right cerebral hemisphere there were found lying side by side, in a horizontal position, a piece of No. 20 brown wire two and one-sixteenth inches in length, and a large button needle with a piece of black linen thread attached. No traces of former lacerations of the brain-substance could be detected, but in the neighbourhood of the thread the cerebral matter was broken down and discoloured. Transfixing the brain vertically in the frontal lobe, immediately in front of the fissure of Sylvius, but not wounding the corpus striatum or the island of Reil, were another piece of wire, and an imperfect four-penny finishing nail, flat pointed and headless, measuring one-fifth of an inch in width at its broadest part. All the foreign bodies were more or less insulated by gelatinous substance closely adhering to them. Waters was strong, healthy,

vigorous, well formed, witty, and of kind social qualities to the last, having a fine manly figure, a well-developed brain, weighing, after drainage of the first extreme congestion, fifty-six ounces.

On reading this remarkable case one knows not whether to admire most the 'charmed' character of of the life borne by Thomas Waters, the ingenuity of his attempts at self-destruction, the liberality with which lethal weapons were supplied to him in the Kansas Prison, or the sublime indifference to detail in everything, except the length of the wires, with which the report is drawn up.

J. CRICHTON BROWNE, M.D.

DUGAS ON THE TREATMENT OF MANIA À POTU.—In a paper read before the Medical Association of Georgia, Dr. A. L. Dugas (*New York Medical Record*, April 1, 1876) describes his treatment of this affection. It consists in administering cold affusion once or twice a day, giving such food as may be relished, and at times two or three small glasses of toddy. If the patient be very unruly, one or two intelligent persons should attend him day and night as long as may be necessary. For the affusions the patient is stripped of all garments and seated in a tub, and the physician then pours one pitcherful after another over the head in a regular stream, which will pass down over the entire body. The affusion is to be continued from one to three minutes by the watch. The pulse, at first full and strong, soon becomes small and frequent. The physician should watch this carefully, and cease whenever the patient is entirely rational and the pulse sufficiently subdued. After the patient is rubbed and dried, and the room darkened, he will generally sleep six or eight hours, and awake perfectly rational. With the exception of toddy, all narcotics are eschewed in the management of the case.

[This method of treatment appears to bear a strong resemblance to the old-fashioned treatment of the drunkard, which consisted in placing the patient's head under the pump, a proceeding usually having a remarkably sobering effect.—*Rep.*]

OBSTETRICS AND GYNÆCOLOGY.

HEGAR ON THE REMOVAL BY HYSTEROTOMY OF LARGE FIBROID TUMOURS.—In the *Berliner Klinische Wochenschrift* for March 20 and 27, and April 3, Professor Hegar relates two successful cases of this operation. The first patient, aged thirty-three, had been married two years. For three years she had noticed a swelling of the abdomen on the right side. The menses had been regular until the end of April, 1875, when they ceased. The enlargement of the abdomen rapidly increased from that time. In

July, a superficial examination was made, and a hard tumour closely connected with the uterus, and extending above the umbilicus, was discovered. At the beginning of September, the state of affairs had much changed. The abdomen was now much more and very irregularly, distended, and the superficial veins were enlarged, especially upon the left side, which was most prominent. A hard nodular tumour was felt in the left loin, extending to the middle line, midway between the umbilicus and ensiform cartilage, and having its long axis transverse. Strong friction could be produced by moving the abdominal walls over the tumour. On the right side of the abdomen a second fluctuating swelling could be felt, reaching as high as the umbilicus. Over this a maternal souffle and foetal heart-sounds were detected. The tumour on the right side was punctured with a fine trocar. The cannula brought away some shreds which showed involuntary muscular fibres, and much fatty and disintegrating tissue. It was therefore concluded that the tumour was a fibroid commencing to break down, and that further disintegration was to be feared before the child could become viable. As the patient's general condition was also unsatisfactory, it was decided to induce abortion. A bougie was introduced on October 8, and on the 12th delivery was completed naturally, the foetus being of about six months' development. On November 4, a careful examination was made under chloroform. The tumour had returned to its former position: it was fixed, and the abdominal walls were but little movable over it. By carrying two fingers high up in the rectum, a firm band, apparently a pedicle, could be felt running from the left angle of the uterus to the tumour.

The operation was performed on November 8. The incision extended from six centimètres above the umbilicus to one centimètre above the pubes. Some adhesions of the omentum in front were ligatured and divided. The chain of an écraseur was carried, by means of a bent sound, round the pedicle of the tumour, which was found, as expected, to be a narrow one. The chain was then attached to the écraseur and tightened. The front of the tumour was then separated pretty easily by the hand from the abdominal wall to which it was adherent, and the tumour itself was drawn out of the abdomen. The pedicle was four centimètres long, and three to four centimètres thick, and was attached to the left angle of the fundus uteri. A strong silk ligature was passed through the pedicle for additional security, and the tumour cut off beyond it. When the pedicle was drawn by the ligature and écraseur into the angle of the wound, it was found to have been cut half through by the wire, close to the angle of the uterus, and considerable bleeding took place. It was seen also that the uterus was a good deal enlarged, and contained several other small fibroids: It was therefore resolved to amputate the uterus and ovaries. A double wire was passed through the middle of the cervix; the wires were brought round below the ovaries at each side, and tightened by Cintrat's serre-nœud. Above these, for the sake of security, a third wire was passed round the whole mass, and then tightened and twisted by a serre-nœud, which was afterwards removed. The uterus and ovaries were then cut off; the surface was cauterised; and the stump was fixed in the angle of the wound by two long needles passed through it, and through the abdominal walls, the first two serre-nœuds being left in position. The patient suffered from dragging pain for the first day,

but the temperature never rose above 102° Fahr., nor the pulse above 108, and she recovered well. On the twelfth day, the stump, which had become very offensive, was cut off below the wires. Its remnant was then retracted into a depression four centimètres deep, which began to granulate up as soon as the slough had separated. On December 9, the patient left her bed.

The second case was that of a woman, aged forty-two, who had had three children, the last thirteen years previously. Enlargement of the abdomen had been noticed for seven years, and for many years menstruation had been profuse. For three years the hæmorrhage had been becoming increasingly severe, and no treatment was of any avail in checking it. The patient also suffered much from the weight of the tumour, and was very anxious for its removal. Her general condition was favourable, although there was marked anæmia. The tumour was hard, uniform, and movable, reaching to half-way between the umbilicus and ensiform cartilage. By vaginal and rectal examination, it was made out that the growth seemed to spread out immediately from the internal os uteri. A diagnosis was made of an interstitial fibroid, in which the uterus was incorporated, but without any notable adhesion to surrounding parts.

The operation was commenced by an incision extending from 2½ inches above the umbilicus to 0.4 inch above the pubes. The tumour was without much difficulty drawn out of the abdomen by tenaculum-forceps, but great tension was thus placed upon its short neck. The broad ligaments were lax, and attached to the tumour high up. It was found possible to pass a double wire through the neck of the uterus, and to fasten one wire on each side below the ovaries by means of a serrenœud, which was left in position. As in the former case, a third wire was passed round the whole for the sake of security, and the tumour cut away. It was now found impossible to pass a needle beneath the ligatures, but it was necessary to carry it through the abdominal wall, and through the stump above the constricting wires, which were drawn inward with very great force, so that the ends of the serrenœuds were buried, and their stems cut a groove in the abdominal walls. The wires were tightened from time to time, and on the eleventh day the gangrenous tissue was cut away and the serrenœuds were removed, leaving the divided wires in the stump. On the twelfth day the transfixing needle was also removed, since it was cutting deeply into the abdominal walls. The result of this was unfortunate, for the stump became retracted into a very deep depression, and rigors and febrile symptoms followed. The wires that remained were, however, drawn up and fixed to a piece of wood; the stump was cut off below them on the fourteenth day, and the patient after this progressed well. She left her bed on the forty-first day.

The author believes that hysterotomy, performed after the method adopted in these two operations, will displace ovariectomy from the prominent position which it now holds in surgery. On account, however, of the great breadth of the stump, and its richness in vessels, it is far more difficult to manage than the pedicle of an ovarian tumour, so that the dangers of hæmorrhage and of septic infection may be avoided. Professor Hegar considers that it is preferable to make an incision, if necessary, nearly to the ensiform cartilage, rather than to attempt to

diminish the tumour after the plan of Péan, who recommended that wires should be passed through so as to isolate parts of it, and that these should be cut away in succession. He thinks, however, that the chain of an écraseur may in most cases be passed round the base, and the tumour might then be divided without fear of hæmorrhage. The method of Péan, on the contrary, he believes to afford no security against bleeding.

A. L. GALABIN, M.D.

CROMBIE ON THE CAUSE OF THE COMMENCEMENT OF PARTURITION.—Dr. Charles M. Crombie, in a paper read before the Aberdeen Medico-Chirurgical Society, dilates on the little that is known on the subject. Sir James Simpson's theory that disintegration of the decidua is the cause of labour is, he says, but a part of the truth; it stops very far short of a consistent explanation. As regards the manner in which labour sets in, it is important to notice the absence of any sudden or eruptive element. It is a gradual and regular increase which makes the stages of labour. During pregnancy there is a constant struggle between the uterus and ovum, which the uterus at last terminates by the eviction of the latter. In support of this, the following arguments are adduced.—1. The growth of the muscular tissue of the uterus is not consistent with a state of absolute torpor of the same; action advances muscular development, inaction retards it. 2. The phenomenon of abortion or premature labour points to an unceasing power of expulsion. 3. The sensation of 'quickening' is to be referred to uterine action, since 'quickening' may take place so early as the end of the second month, when the fœtus has no inherent motion: hence the so-called foetal movements are uterine contractions. 4. Lastly, Dr. Crombie points to the gradual approach of the actual process of parturition, under the form of 'false pains,' supervening some days before the positive symptoms of labour commence.

Looking at the gravid uterus from a dynamical point of view, Dr. Crombie says the ovum is retained by means of the hydrostatic action of the liquor amnii, which distributes the pressure exerted on it by the uterine contractions equally in all directions; when the balance between these opposing forces is lost, labour results.

FANCOURT BARNES, M.B.

CUMMING ON THE UTERINE SOUFFLE AND THE FETAL HEART.—Dr. James Cumming of Edinburgh, in a paper read before the Obstetrical Society of that city, remarks that the uterine souffle is a 'symptom' and not a sign of pregnancy. He considers that the theory that the souffle is produced by the vessels which ramify in the uterine walls is correct. Inasmuch as Carrière and Collins heard the souffle, the one twenty-four, the other forty-four hours, after the expulsion of the placenta, Dr. Cumming rejects the theory of the souffle arising from the utero-placental site. Dr. Cumming has also arranged tables showing the relation between the number of pulsations of the foetal heart, and the weight of the child; from which he concludes there is a relation between the weight and pulsations of the fœtus *in utero*. From several cases in which he has made observations, Dr. Cumming has found no relation between the foetal and the maternal pulse. In conclusion, he believes that the indications from auscultation of the foetal heart are of a certain value in the diagnosis of the sex of the fœtus *in utero*, but cannot solely be relied upon.

PREWITT ON MENSTRUATION FROM THE PEDICLE AFTER OVARIOTOMY.—Dr T. F. Prewitt of St. Louis relates in the *American Journal of Medical Sciences* for April, the case of a woman aged thirty-nine, who first perceived a tumour in the abdomen immediately after confinement in August, 1864. Between that time and October, 1874, she had two labours at full term and one miscarriage, and was tapped four times. In October, 1875, ovariectomy was performed; and the pedicle, a long narrow one, was clamped outside the wound. In January, 1876, she called on Dr. Prewitt, looking improved in health and rapidly gaining flesh.

A small red granulating tumour as large as a small cherry projected at the site of the pedicle, and from this a discharge of blood took place at each menstruation, and continued during the whole of that period. She was then menstruating for the third time since the operation, and this phenomenon had occurred during each of the periods. Menstruation was otherwise normal.

DERMATOLOGY.

PIFFARD ON THE TREATMENT OF THE SCROFULIDES (LUPUS).—Dr. Henry G. Piffard (*American Practitioner*, December, 1875), adopts the pathology and nomenclature taught by Hardy, and the treatment of Hebra. For the cauterisation of the smaller tubercles he uses 'a probe made of irido-platinum. The point of the needle is dipped in fused nitrate of silver, a thin layer of which immediately congeals around it. As soon as it is cold, a second or a third dipping will increase the deposit of silver sufficiently.

With these needles quite small punctures may be made, and are less painful than those made with the ordinary silver stick.'

SCHIEBER ON PELLAGRA IN ROUMANIA.—Scheiber (*Vierteljahresschrift für Dermatologie und Syphilis*, 1875) observes that pellagra is common in Roumania, there being 84 cases amongst 2,500 hospital patients. The disease does not occur amongst the poor exclusively, and, although maize is a common article of diet, many of the patients have other and good food. The author does not believe that the malady is always produced by the use of maize, considering that bad hygienic conditions, telluric and individual peculiarities, play an important part in its origin. It is generally stated that more women than men are affected, but Scheiber found in 136 cases 94 males and 42 females.

BOECK ON JUNIPER FUMIGATIONS IN THE TREATMENT OF SKIN-DISEASES.—Dr. Cäsar Böeck (*Vierteljahresschrift für Dermatologie und Syphilis*, 1875, 4 Heft) describes the following mode of treatment. The surface of the body is subjected to the action of the fumes of moist juniper leaves in cases of prurigo, urticaria, and pruritus cutaneus, with great mitigation of the itching. For example, a woman fifty years of age had been tormented with urticaria from March to September, and was obliged to scratch herself for about an hour every evening before going to sleep. The usual remedies had been fruitless. After two fumigations she was better, after ten* (one daily) she left off scratching and no more fumigations were required.

REPORTS OF FOREIGN SOCIETIES.

IMPERIAL ROYAL SOCIETY OF PHYSICIANS IN VIENNA.

February 18. *Demonstration of Gynecological Preparations.*—Dr. Funk demonstrated some preparations, and made remarks on diagnosis and therapeutics. He said that now, when the technical part of the operative surgery of women had reached such a state of perfection, special care was demanded in regard to diagnosis and the indications for operation, as much still remained unknown in respect to these. He remarked that the diverging opinions on the effect of an operation, especially a new one, were usually only attributable to the fact that the operation was performed where it was contra-

indicated. He referred to the rapid dilatation of the female urethra for therapeutic purposes, frequently performed in England, but rarely in Austria, although the operation was followed by very good results in cases of great irritability of the bladder, where other means failed. He also referred to the divergent views held as to the efficacy of Hildebrandt's plan of treating uterine myomata by the subcutaneous injection of ergotin, and said that the difference was due to nothing else than the use of the remedy in unsuitable cases. Another instance was the operation of supracervical amputation of the uterus, which was altogether rejected by Scanzoni, although Péan had performed the operation in twenty cases, of which fifteen were successful. Here also the cause of the difference of opinion lay in the want of care as to the indications. Dr. Funk also remarked that, in addition to diagnosis, the determination of the proper time for operation was important, as, from want of attention in this respect, even harmless operations, such as puncture of ovarian cysts, might in some circumstances be attended with danger. It was also necessary, before proceeding to operate, to take into account all the eventualities which might happen. Some of the preparations which he would demonstrate proved the importance of this. He would first make some remarks on the preparations and on some gynecological operations.

Laparotomy, frequently employed in recent times, was performed: 1. for the removal of extra-uterine fetuses; 2. for the relief of internal incarceration, and for the removal of diseased, and sometimes even of normal, organs. In regard to extra-uterine pregnancy, he said that operative proceedings in pathological conditions were the less to be dreaded in the present day, as the peritoneum had generally undergone such changes that an operation could be performed without danger by following Lister's method. With regard to the diagnosis of extra-uterine pregnancy, he referred to icterus as a symptom occurring in cases in which the fetus had continued to grow for two or three months, the membranes then rupturing, and its further development being arrested. He had met with it in three cases, though it was not referred to by other authors; it was probably caused by the absorption of altered blood-colouring matter into the blood. In cases of extra-uterine pregnancy, the condition of vaginal portions of the uterus often resembled that found in cases of intra-uterine tumour. Passing to laparotomy in cases of internal incarceration, he referred to a case of Professor Klob, in which the obstruction was produced by an abnormal band; and pointed out that it must be remembered that such a band might contain a diverticulum of the intestines, as was the case in a preparation which he showed, taken from a girl nineteen years old, in whom a band of false membrane passed from the intestines to the uterus and contained a diverticulum. If this had caused incarceration and an operation had been performed, the band and diverticulum would have been divided, and the patient, rescued from one danger, would have been exposed to another of not less magnitude.

Speaking of the operative treatment of myomata by supracervical extirpation of the uterus, he said, while this operation in the case of subserous tumours was easier than ovariectomy, inasmuch as slight adhesions were generally present, it was more dangerous, as a more extensive abdominal incision was necessary, and the hæmorrhage and subsequent shock

were more unavoidable. In such operations it was necessary always to have restoratives at hand. It was especially worthy of remark, that in cases of uterine myoma other diseases were frequently observed. Thus in 200 patients suffering from uterine tumour, in fifty he had found heart-disease, generally valvular; in thirty-two Bright's disease; in thirty cancer of various organs. He was not able to find any etiological connection between the diseases; and he believed, that in certain cases of valvular disease the venous hyperæmia of the uterus must contribute much to the development of the tumours. Before operating, therefore, on uterine tumours, the previous diseases of the patient must be inquired into. The operation of removing new growths from the cavity of the uterus was indicated in many cases, but should never be performed when parametritis was at the time present.

He related a case which had come under his observation, in which a woman, aged twenty-six, after confinement, had an offensive discharge. The *post mortem* examination showed that this did not proceed from decomposition of retained foetal membranes, but from carcinoma of the uterus. He regarded extirpation of the uterus as indicated in many cases of cancer of the organ, because the operation had already been several times successful, and because the cancer was usually solitary (in eighty-six cases out of 120). The operation was contra-indicated when the disease had spread widely, especially in the neighbourhood of the ureters, and in so-called cauliflower excrescence, as this could be removed by a simple operation.

Finally, Dr. Funk remarked that, when a sound passed into the uterus was found to have entered the peritoneal cavity, it was not to be always concluded that it had passed along the Fallopian tube or penetrated a diseased uterus; there might, as occurred in a preparation which was shown, be a fistulous opening in the uterus, resulting from the bursting of a parametritic abscess.

Hegar's Injection-Apparatus.—Returning to the subject of Hegar's injection-apparatus (see LONDON MEDICAL RECORD for April, page 179), Dr. Mader related an experiment in which he produced an artificial stricture of the colon in the dead body, and allowed water to flow into the bowel. Under slight pressure, the water reached the small intestine; and it was only when the opening of the stricture was a line in diameter that the flow was obstructed. He also produced artificial intussusception, and tried the effect of injecting water into the intestine. No result was produced. He had found the injection of medicines into the intestine very useful in a case of dysentery. He had also made, with negative results, experiments on the effect of injecting carbonic acid as a sedative in cases of uterine cancer. Applied externally, carbonic acid had given relief in cases of articular rheumatism.—Dr. Stoerk said that he had injected carbonic acid into the bladder in cases of painful affection of the organ, with no other result than that of increasing the pain.—Dr. von Basch remarked that carbonic acid had been used as a local application many years ago, but that its employment had been abandoned on account of the want of results.—Dr. Langer said that the injection of carbonic acid into the uterus had been twice followed by death, the cause of which could not be found on *post mortem* examination.

February 25. *Polypi of the Urethra.*—Dr. Grünfeld showed a patient (male) with a polypus of the

mucous membrane of the urethra. These new growths, which occurred both in the male and in the female urethra, usually produced symptoms apparently belonging to very different diseases, and therefore obstinately resisted treatment. Even examination by a metallic or elastic instrument did not generally detect the existence of very soft growths. It was when the vegetations increased in size that their presence first became noticeable. Polypi and condylomata of the urethra generally gave rise to symptoms of gleet; or they more or less completely blocked the urethra and thus simulated stricture. The introduction of an instrument readily produced hæmorrhage; or the growths led to sloughing and perforation, with fistula, as in a case reported by Beyram. In a case related by Roger, retention of urine set in twenty-four hours before death. At the *post mortem* examination, the urethra was found filled with polypoid growths from the external orifice to the bulb. The diagnosis of condylomata or polypi in the urethra, especially at the commencement of their development, was impossible before the invention of the endoscope. In May, 1873, Dr. Grünfeld found, in a patient with gleet, a condyloma larger than a hemp-seed eight or ten centimètres ($3\frac{1}{2}$ or 4 inches) from the external orifice; after its removal, by excision, the symptoms disappeared. In another case, five or six small proliferating condylomata of the mucous membrane of the urethra were cured by cauterisation. In the case now exhibited the endoscope showed, six centimètres from the orifice, a growth about the size of a linseed; the surface was purely granular, and presented numerous small vessels. There were also similar growths at the internal orifice of the urethra. In 1874, Fürstenheim of Berlin detected polypi in the urethra by means of the endoscope. Ebermann had also made an observation on the subject.

Extensive Development of Cysticerci.—Dr. Chiari showed preparations taken from the body of a man, aged sixty-five, who, during his short sojourn in hospital, presented but few symptoms which could lead to the diagnosis of the disease which was found to exist. Up to a short time before admission he had been in good health. For some days he had been melancholic, and on February 15 he had an epileptic attack. In the hospital the epileptic paroxysms increased in number, amounting at last to twenty or twenty-five in a day; at last he became unconscious between the attacks, and died in a state of coma. It was imagined that the case was one of cerebral tumour, ending in inflammation.

At the necropsy, numerous superficial subcutaneous protuberances were found, over which the skin was readily movable. On section, they were found to consist of vesicles of the size of peas, containing a whitish point in their interior. There could be no doubt that the case was one of multiple formation of cysticerci. Further examination detected similar bodies in the muscles of the trunk and limbs, in the subcutaneous comatose tissue, in the substance and in the ventricles of the brain, in the meninges and between them, and in the heart; scattered ones were found in the cutis, pericardium, and mesentery; none in the spinal cord and its membranes, in the lungs, liver, spleen, kidneys, and intestine. All the cysticerci were similar in size, and from their smallness it was concluded that infection must have taken place not long before death. Nothing could be discovered regarding the source of infection. [Nothing is said of the microscopic character of the growths.]

A New Modification of the Plaster of Paris Bandage.—Dr. Zsigmondy described and demonstrated his method. A bag, having sewn over it a layer of calico and linen, and over this a piece of flannel, is filled with plaster of Paris, and immersed in lukewarm water for about a minute and a-half, until the gypsum is thoroughly moistened. The air is pressed out through a small opening, the bag is removed from the water and laid on a flat surface, the gypsum being equally spread by the hands and the folds flattened out. The bag is then applied with the flannel towards the body, and fastened with rollers. The time required for solidification varies from ten to twenty minutes, according to the quality of the gypsum. The thickness of the gypsum in the bag should be about seven millimètres ($\cdot 28$ inch). When the application is to be made to angular parts, such as the heel, slits are cut, and pieces of flannel and linen sewed in. The folds frequently formed in the flannel give no trouble to the patient, and the pressure of the splint is equally diffused. When the dressing is changed, the splint should be accurately replaced in the former position, which, for this purpose, should be previously marked out by ink. If it be desired to form a trap-door in the splint, a single or (better) a double suture should be made at the part. In this way single spots may be kept moist, or a fenestra may be made either before the filling of the bag with gypsum or after setting. The bags can be rendered impermeable by tinfoil, but the process is troublesome and occupies time. Impregnation with stearin and copal is less effectual.

Some examples were given of the modifications of which the dressing is capable, among which were a Petit's boot, with an isolated fenestrated trap-door, in a case of fracture of the leg; a capsule with two trap-doors for a knee-joint; a splint with pelvic band for a fracture of the thigh; a bodice half filled with gypsum and provided with buckles and axillary straps for fracture of the ribs; a ring with a long thumb-shaped process for dislocation of the lower end of the ulna, etc.

Meissner's Plan of Ventilation.—Dr. Zsigmondy showed the action of Meissner's ventilation apparatus in a model of a hospital ward intended for the Philadelphia Exhibition.

ACADEMY OF MEDICINE IN PARIS.

March 23. *Dicrotism and Polycrotism.*—M. Marey read a report on a paper by Dr. E. Maragliano, of Bologna, on dicrotism and polycrotism. The author called to mind that the ancients had thoroughly appreciated the clinical value of the dicrotic pulse, which the graphic method had given the power of studying from the physiological aspect. He contested the theory of normal dicrotism formulated by M. Marey in 1863, which, however, had been for some time abandoned by its proposer from considerations analogous to those developed by the Italian experimentalist. According to M. Marey, dicrotism of the pulse depended—1. On the velocity acquired from the column of blood projected into the arteries; 2. On the elasticity and reaction of the vessels inducing an alternately centrifugal and centripetal oscillation. In other words, the shower transmitted by the ventricular systole to the aorta met with obstacles at the periphery and retrograded towards its starting-point, where it found a fresh obstacle, at the retracted sigmoid valves, whence a fresh peripheric shower was

produced without the intervention of the cardiac systole.

April 4. *Leprosy*.—M. Ruz de Lavijon, *à propos* of a patient shown by M. Desprès, made some remarks on leprosy. He said that when the leprosy has attained the stage of sphacelus, the disease is sufficiently characterised by anterior signs not to admit of any doubt. The countenance at this stage is characteristic. The skin is thickened and bronzed. The hair and the eyelids fall off, and the teeth fall out; the ears are enormously enlarged; the nose is almost invisible, in consequence of the fall of the septum; in a word, the features present that peculiar appearance which has given rise to the comparison of the countenance of the leper with that of the lion (leonine leprosy). Besides the classic leonine leprosy, other so-called leprous conditions of the skin exist. In many countries, also, every repulsive affection of the skin, especially of the face, is styled leprosy. It is by no means demonstrated that leprosy is contagious; and if the small number of cases of leonine leprosy in the countries where it is not rare, notwithstanding the absence of all measures of isolation, be considered, its contagiousness does not seem very probable. The heredity of leprosy is also an insufficiently studied point. We hear of families in which there have been one or two lepers, but there are no true families of lepers. With regard to the geographical distribution of leprosy, it seems specially to exist in alluvial districts; it is met with under the equator and at the poles, at the Antilles and in Norway; it is not a climatic disease, but rather, like cretinism, a disease of locality.

Lead-Colic amongst Creoles.—M. Larrey read for M. Bérenger-Féraud a note on lead-colic amongst the creoles of Martinique. Dutrouleau had denied its existence amongst the creoles. The writer supported it by eight cases; he explained the difference of his opinion from that of M. Dutrouleau by the fact that the latter made his observations at the Antilles at a time when the local steam-boat traffic was but little developed, and when the creole engineers and stokers were very few in number, so that at that time the disease was almost exclusively observed amongst the Europeans. Since steam-engines have become general in the Antilles, and the local steam-boat traffic has developed itself, creoles have been employed to attend to the machinery, and lead-colic has shown itself among them as amongst the Europeans. Therefore Dutrouleau was in error in ascribing immunity to the creoles. On this subject, M. Gubler related an interesting account of a family of creoles recently arrived in Paris, and who had been under his care fifteen years. Every member of this family, consisting of seven or eight persons, with the exception of the father, had been attacked by a species of epidemic, which they said was rife in their country, and several of the children had died. M. Gubler ascertained in the case of the mother and two of the daughters the existence of true lead-poisoning, and of paralysis of the extensors of the hands. The cause of this poisoning was sought for in vain. One day one of the girls, who had a sty on her eye, put on it the half of an hard-boiled yolk of egg, a common remedy in the West Indian colonies. The next day the skin of the patient's eyelid had become perfectly black. M. Gubler found that she, as well as her mother and sister, was in the habit of powdering her face with a powder imported from the colonies, and which was also used to powder children. The druggist of the place made and sold this powder

wholesale. M. Gubler had it analysed, and found that it contained 20 per cent. of white lead. The cause of the epidemic complaint was found, and the druggist was obliged to cease from his pernicious traffic, which had already caused the death of a large number of children. The fact tended to confirm the opinion of M. Lefèvre, of Brest, that the dry colic of hot countries is nothing but lead-poisoning. M. Gubler, however, was of opinion that dry colic, not caused by lead, does really exist.

ACADEMY OF SCIENCES IN PARIS.

Feb. 21.—*Application of the Graphic Method to the Phenomena of Digestion*.—M. H. Toussaint submitted to the Academy a memoir on the application of the graphic method, to the determination of the part apportioned to the respiratory apparatus in the performance of some mechanical acts of digestion.

The Excitability of the Heart.—In a fresh note on the excitability of the heart, M. Marey demonstrated that that organ undergoes, at each phase of its revolution, changes of temperature which modify its excitability. He said that experience shows that the excitability of the heart, like that of the other muscles, increases and diminishes with the temperature, but it is also found that the excitability of the heart changes with the different phases of its revolution. We are therefore led to ask, does not the temperature of the heart vary at the different moments of its revolution? and, on the other hand, is not the bearing of these variations such that the lowering of the temperature corresponds with the phase of least excitability? Experiment has verified both these suppositions. The heart becomes warmer whilst it performs its mechanical work, and cools when it relaxes its action. The moment at which the heart will be lowest in temperature, and consequently least excitable, will be that in which it will have accomplished its period of cooling. This then will be the commencement of the systolic phase. Here again theory and experience are entirely at one.

Borax as an Antiseptic.—M. Dumas communicated a letter from M. Schnitzler on the antiseptic properties of borax. The writer called attention to the following facts. Mr. Arthur Robottom, of Birmingham, had found in Southern California a deposit of borate of soda, accompanied by borate of lime and sulphate of soda. Near this deposit he found the carcass of a horse, which had been there for four months and was in perfect preservation, notwithstanding the great heat.—At the dairy farm of Lodi, Signori L. Manetti and G. Musso made four series of experiments on the use of salicylic acid—1. In the keeping of milk; 2. the separation of the cream; 3. the keeping of butter; 4. the preparation of cheese with ordinary rennet. The writers came to the conclusion that borax offers the same advantages as salicylic acid, and is more easy of employment in consequence of its being cheaper than that agent.

Coagulation of the Blood by Carbonic Acid.—MM. E. Matthieu and V. Urbain presented a fresh note on this subject. M. Glénard, at the meeting of November 15, 1875, wished to show that carbonic acid is inert, because the plasma of the blood remains liquid when the vein is plunged into carbonic acid. The writers noted that carbonic acid passes but slowly through the walls of the vessels, and that a high temperature or a considerable time is necessary to obtain the coagulation of the blood in this way

They specially brought against M. Glénard the following experiments. A certain quantity of blood, as it leaves the vessels of a dog, is received into the stomach of a fowl properly prepared. This is shaken during five minutes, so as to allow by exosmosis the exit of the chief part of the carbonic acid. Finally, the blood is divided into two glasses; the first is traversed by a current of air or any other neutral gas; a current of carbonic acid passes through the second. This latter is coagulated in a few seconds, the temperature of the medium being 95° Fahr., whilst in the first the blood remains completely liquid. A similar experiment may be made with plasma, by receiving some horse's blood, as it leaves the vessel, in glass tubes of which the diameter does not exceed two centimètres, and which are plunged into ice; coagulation does not ensue; at the end of a certain time a completely colourless plasma may be collected from these tubes. If a current of air deprived of carbonic acid be passed through this plasma, diluted with at least five times its volume of water and kept at 32° Fahr., it is possible to deprive it of the largest part of its acid gas; after that it may be brought back to the ambient temperature without there being coagulation, but this occurs when carbonic acid is brought into contact with the liquid.

March 6. *Antiseptic Properties of Madder Root.*—M. de Restaing read a note on the antiseptic properties of madder root. A specimen of meat had been preserved from July 27, 1875, to February 27, 1876, in a jar containing powdered madder, which was opened a dozen times to verify the results obtained. The weight of the meat had decreased from 119 to 25 grammes, without any smell or any development of living organisms having shown themselves. From these experiments, the author thought it would be advisable to institute similar trials for the preservation of dead bodies; perhaps by this method means might be found of conciliating the presence of cemeteries in the vicinity of great cities with the sanitary conditions which now so greatly occupy public attention.

Calorific Action of certain Regions of the Brain (the vaso-motor systems situated at the surface of the hemispheres).—The summarised results of the experiments made by MM. Eulenburg and Landois were the following.—1. The destruction of certain anterior cortical regions of the brain is followed by a very considerable augmentation of temperature in the extremities of the opposite side. This increase shows itself immediately, even before the wakening of chloroformed animals and before the performance of any spontaneous movements; it may amount to 5° or 7° Cent. (about 9° or 12° Fahr.) It is also observed that it shows itself more clearly, sometimes in the fore, sometimes in the hind, paw; the result depends specially on the situation and the extent of the portion destroyed, as well as on the relative importance of the destruction. 2. The active calorific region of the cortical surface, specially comprises the posterior and lateral part of that great uniform convolution, answering in the dog to the anterior central fold in man and apes (post-frontal convolution of Owen). The regions acting on the anterior and posterior limbs are separated from each other. The former is situated slightly forward and at the side. The superficial destruction of the folds situated in front has no heating effect, or this effect is very weak, and probably secondary. In the same way, destruction of the posterior and occipital pos-

terior convolutions is not followed by any calorific effect in the limbs in question. 3. After the destructions followed by successful results, disturbances of motility and of muscular sense in the extremities of the opposite side are mostly observed when the chloroformed animals regain consciousness; these disturbances apparently depend on the lesion of the motor apparatus situated in the same region of the hemispheric surface. 4. The increase of temperature in the opposite limbs is generally kept up some time after the lesion, although gradual and very decided differences of that kind, from two days to several weeks, exist. 5. The isolated electric excitation of the cortical region in question, performed with rather weak currents, is followed by a very weak and very evanescent lowering of the temperature, though easily appreciable by the thermo-electric method, in the extremities of the opposite side. This lowering, which varies from 0.2° to 0.6° Cent., is equally produced on curarised and non-curarised animals; it is therefore independent of the motor action of the irritant. 6. Irritation and the destruction of the spinal marrow (lumbar region) and the peripheric trunks (sciatic nerve), performed at a somewhat long interval after the destruction of the above-named regions of the brain, and the re-establishment of the uniformity of the temperature, still act in the usual manner on the temperature of the posterior extremities.

Biliary Salts.—MM. Feltz and Ritter presented another note on the biliary salts, concerning their action on the pulse, tension, respiration, and temperature. By injecting natural bile into the blood in non-poisonous quantities, they found that the pulse diminished in frequency, that respiration slackened, and that temperature and arterial tension fell. Injections of the different colouring matters of the bile and of ethereal solutions of cholesterine did not produce the same effect, whilst the biliary salts acted like natural bile. The biliary salts acted principally on the blood, and by its intervention on the muscular system; they modified the corpuscles, and however small might be the quantity of the biliary salts, their injection had the effect of retarding the passage of the blood in the capillaries.—M. Bouillaud remarked that these experiments clearly showed the reason for that slackening of the pulse which he had pointed out in icteric subjects.

March 13. *Chloroform in Cholera.*—M. Desprès presented, in competition for the Bréant prize, a memoir on the use of chloroform in the treatment of cholera.

REVIEWS.

Thérapeutique des Maladies Vénériennes et des Maladies Cutanées. Par M. P. DIDAY et M. A. DOYON. Paris: 1875.

This work consists of two parts, which are so disconnected that they might just as well have been published as separate volumes. The first part, by the well-known Lyons syphilologist, M. Diday, is a comprehensive treatise on the treatment of venereal diseases. It is eminently practical, and does not disdain to descend to minute particulars regarding methods of treating patients, and, what is another thing, their maladies, which an English surgeon would hardly have imagined, and if he had, would certainly not have published. The general practitioner who is called on occasionally to prescribe for

this class of affections, and whose experience is necessarily limited, will find some admirable rules of treatment in this book.

In the section on gonorrhœa, the indications for the administration of copaiba are clearly pointed out. The drug should never be given until the disease is matured; and that the proper time has come is recognised by a peculiar character of the discharge. A drop is taken between the forefinger and thumb, and can be drawn out by the separated fingers into a thread at least a centimètre long. If the drug does not cure after a week's trial, it should be given up for a time.

M. Diday believes in three kinds of syphilitic sore. What is known as the soft sore he designates a *chancrelle*; for the infecting sore he reserves the term *chancre*. A sore produced on a person already syphilitic by inoculation with the true syphilitic virus, he names *chancroïde*. The *chancroïde* has all the characters of the infecting chancre, but there is no affection of the glands; it has the physiognomy, but wants the essence of the chancre. When syphilis is not cured after the secondary stages, it becomes a *diathesis*, and the tertiary symptoms are the manifestations of this diathesis.

Mercury is very lukewarmly recommended, the author believing that the inconvenience and injury connected with the treatment are not often compensated by benefit to the disease. He discusses the question at great length. When he does give mercury, he prefers the proto-iodide to any other form, and condemns mercurial inunctions. He attributes great weight to strengthening remedies, change of air, and the use of mineral waters, as assisting the cure.

M. Diday is a firm believer in syphilitic germs. 'I believe,' he remarks, 'that syphilis results from the presence in the blood of microphytes or microzymes (yet to be discovered). If mercury cures the lesions which exist without being able to prevent their return, it is because, like all parasitides, it destroys these minute essences when they are alive, but can do nothing against them when they are in the state of germs or eggs (*à l'état de germes, d'œufs*). We fear M. Diday is not such a reliable authority on germs as he is on gonorrhœa.

M. Doyon's section on the treatment of skin-diseases is the product of great industry, but does not display much method in selection. The works of German and English dermatologists have been laid under contribution, with a liberality that is unusual with French writers in this department of medicine. The result is an accumulation of details regarding all kinds of remedies, which, to those who read the book for practical guidance, must be very perplexing. Whilst M. Diday's section bears evidence in every page to the observer and man of practical experience, M. Doyon's bears testimony chiefly to his diligence as a compiler. He regards 'scrofula, lymphatism in its different degrees, anæmia, an asthenic or debilitated constitution,' as being obstacles in the cure of many skin diseases. These conditions are amenable to the waters of Uriège, where M. Doyon is *médecin-inspecteur* of the waters.

Lehrbuch der Hautkrankheiten. Von Dr. ISIDOR NEUMANN. 4th edition. Vienna: 1875.

The publication of the earlier editions of this standard work on skin-diseases coincided with the period during which the first edition of Hebra's great

work was out of print; and the increasing fame of the Vienna school of dermatology ensured the success of the only available book, in which its doctrines were expounded. The work itself supplied admirably the want that was felt, being lucid, concise, and practical. It went rapidly through three editions, before the most important volumes of the new edition of Hebra's book appeared. With their appearance, however, Professor Neumann's work had to rest entirely on its own merits, which probably explains the otherwise somewhat obscure sentence in the preface to the fourth edition, in which the author informs us that he had delayed publishing it for a year after the previous one was exhausted, in order to learn with certainty whether his book really supplied a want or owed its reputation to accidental circumstances. Numerous demands taught him that the book still supplied a want, and we believe that the want is really felt. Notwithstanding its increase in size, it is still much smaller than Hebra's classical work, and a shorter book has always the advantage over a long one. Its intrinsic merits are such as to place it among the best text-books of skin-diseases which exist in any language; and the care with which the present edition has been brought up to the most recent advances in dermatology, must secure for it the attention of all who are interested in that branch of medicine. It contains ten additional woodcuts, illustrating the pathological histology of the skin. These woodcuts have formed a special feature of Dr. Neumann's book, although we can hardly say the most satisfactory one.

The 'cell-infiltration' and 'cell-growth along the vessels,' which, with figures intending to illustrate this condition, are repeated frequently in the earlier editions, as explaining the pathology of many very different skin-diseases, are not definite enough to convey any accurate idea of a characteristic pathological condition. The woodcuts added in the present edition are more instructive than the previous series. Some, especially those illustrating the pathology of the acne which in some cases follows the use of bromide of potassium, are of great interest. Amongst the new ones, we may mention one illustrating the changes which were seen in a section from the axilla in a case of pemphigus, the most conspicuous features being the usual cell-exudation and much enlarged sweat-glands. We doubt whether, in regard to the latter, Dr. Neumann has sufficiently borne in mind the fact that in the axilla, when the skin is normal, the sweat-glands are of enormous size. Scleroderma and ichthyosis find also additional illustration.

The investigations regarding the bromide eruption show that the glands of the skin are specially affected, whence it is inferred that they excrete bromide of potassium when it is taken internally, and are consequently liable to inflammation of their special cellular structures.

The very valuable chapter on the vegetable parasites of the skin is enriched by four woodcuts representing different stages of the Achorion Schönleini, in different stages of cultivation.

The author describes in this edition, for the first time, a disease which, he believes, has hitherto escaped the attention of observers. He gives it the name of *dermatitis circumscripta herpetiformis*, and considers it to be a special circumscribed form of inflammation, affecting the papillary layer of the cutis, and specially connected with changes in the sweat-glands. He has observed nine cases of this disease, whilst Hebra

has, he remarks, only observed one, and that one we do not find has been acknowledged by Hebra as being an instance of a specific disease. Since Dr. Neumann has within a comparatively brief period seen nine cases, the disease cannot be rare; and if he be correct in his diagnosis, not only Hebra, but all other dermatologists, have overlooked a not uncommon and characteristic malady.

We trust that this new and improved edition will meet with the appreciation it deserves, and that Dr. Neumann will never again think it necessary to submit the question of its inherent value to artificial tests.

Leprosy in Jerusalem. — Mittheilungen aus den Leprösen Hütten (Biut el Massakin) in Jerusalem. Von Dr. LONDON, in Carlsbad.

Dr. London, formerly of the Rothschild Hospital at Jerusalem, proposes at a future time to publish his remarks on leprosy as seen in Judea; his present paper is short. He gives a detailed history of a very complete case of leprosy, in which at one time or other all the symptoms of the two commonly recognised forms of the disease occurred. The case ran through the stages of anæsthesia, muscular atrophy, contraction of the extremities, eruptions of pemphigus-like bullæ, production of tubercle, loss of phalanges, sloughing of nasal cavity, etc. The disease was not in this case hereditary; it could not be traced to infection, or to any especial poverty of living.

Dr. London often observed palpable enlargements along the ulnar nerve, and he frequently examined under the microscope portions of skin, and of cellular and of nervous tissue. He found small round cells containing granules, sometimes isolated, but more frequently grouped together; also larger round granules and spindle-shaped elementary tissue, and occasionally an intercellular substance, which, when treated with acetic acid, became granular. These cells he thought to closely resemble morphologically the inflammatory proliferation of cellular tissue, but it differed from it in its mode of aggregation, and in its remaining longer in the border-land between organisation and decomposition.

The leprosy spots appeared symmetrically on the body, first attacking the skin, and afterwards extending to the mucous membranes.

Dr. London considers leprosy to be a deep-rooted disturbance of the whole nutrition of the system; it is certainly not contagious, whereas it is as certainly hereditary, and can be traced in families, sometimes passing over one generation, and re-appearing in the next.

Dr. London was struck with the fact that the districts which produced most malarious fever produced also most cases of leprosy.

He found no mode of treatment specially successful, and was inclined to think that in some cases, where the local symptoms were ameliorated by treatment, the general condition of the patient became rather worse. The leper-huts at Jerusalem are entirely neglected by government; many of them have fallen in, and they are not fit to afford shelter to dogs. There are often more than thirty lepers wearing out a sort of troglodyte life in them, and ending their days by diarrhœa or Bright's disease, or by suffocation owing to the leprosy infiltration reaching the larynx.

J. MACPHERSON, M.D.

Transactions of the Obstetrical Society of London. Vol. XVII. For the year 1875. London: Longmans & Co.

The present volume is one not only of unusual size, but also of unusual interest, containing as it does a *verbatim* report of the prolonged discussion on puerperal fever, which extended over four meetings, and embodies the experience of many of our leading authorities, occupying over 150 pages.

The subject at the time attracted much attention, not only among obstetric physicians, but also among the large body of general practitioners, who are at any time liable to encounter an epidemic of this terrible malady, and whom it therefore behoves to be conversant with the experience of those who have witnessed its ravages, or have given attention to the subject.

The table of contents indicates an evidently healthy state of activity of the society; the communications being of varied and practical interest. Among the more prominent may be noted 'Report of Three Cases of Cephalotripsy,' by Dr. J. Braxton Hicks; 'The Treatment of Rigid Perinæum,' by Mr. Ernest Trestrail; 'Case of Extra-uterine Fibroid,' removed successfully by gastrotomy, weighing 17½ lbs., by Dr. Routh; 'Intramural Calcareous Tumour impeding Labour,' by Dr. A. Wynn Williams; 'Removal of Large Colloid Tumours of the Omentum by Gastrotomy,' by Dr. R. Barnes; 'Cases of General Dropsy in the Fœtus,' by Mr. Lawson Tait, Dr. P. Smith, and Mr. Ashburton Thompson; 'Case of Hydatidiform Mole,' by Dr. John Williams; 'Note on the Treatment of Chlorosis and Anæmia with the Phosphide of Zinc,' by Mr. Ashburton Thompson; 'On Prolapse of the Funis during Labour,' by Dr. G. Roper; 'Case of Epithelioma of the Cervix Uteri complicating Labour,' by Dr. Edis; 'Cases of Ruptured Vagina during Labour,' by Drs. Heywood Smith and Wiltshire; 'Note on the post mortem Diagnosis of Multiparous Uterus,' by Dr. Meadows; and other communications too numerous to mention.

There are several plates and woodcuts to illustrate the text, many of them coloured, and well executed.

The catalogue of the library and museum, comprising over 150 pages, is bound up with the present volume, and will doubtless prove a welcome addition.

The volume in every respect does credit to the Society, and to those who have edited it.

Consumption: Its Treatment by Climate, with reference specially to the Health Resorts of the South African Colonies. By J. A. ROSS, M.D. 1876.

This little work is evidently the grateful offering of one who has derived much benefit from a trip to and residence in, the South African colonies, and is at the same time an attempt to review the whole subject of climate in reference to consumption.

In the former aspect the book deserves much commendation, as containing some good information derived from personal experience and conveyed in a pleasant form. In the latter, the author has succeeded in collecting much material, but has failed in digesting it properly and in drawing careful deductions. Dr. Ross lays great stress on the value of the voyage to and from the Cape, and remarks, we think justly, that while it includes all the best part of the voyage to Australia, it excludes the dangers to which the invalid is exposed in rounding Cape Horn

on the return trip. Dr. Ross visited in succession Cape Town, Port Elizabeth, Grahamstown, and, passing the Katberg range, halted at Queenstown and Dordrecht, and thence proceeded to Bloemfontein and the diamond fields. He made careful inquiries at these places, and found that consumption existed in all, not only among the visitors or recent emigrants, but as a disease developing itself in the settlers after many years' residence. Among these latter, however, it is not common, though an interesting case of considerable standing is adduced; but in the coloured population the mortality from this cause, as shown at the Albany Hospital, Grahamstown, is high.

The Cape physicians, it appears, from an early period have placed their faith in the treatment of phthisis by open air life at a high elevation; and results, Dr. Ross says, have confirmed the wisdom of this practice. Outlines of cases apparently cured by the climates of the elevated stations are given; one of special interest, from the careful report of two eminent physicians of the patient's state before he left London, and the result of Dr. Ross's examination some years later. The patient had quitted England with extensive tubercular consolidation of both lungs, and some laryngeal mischief, forbidden to marry, and with a gloomy prospect before him. He completely recovered, married, has a large and healthy family, and is active and able for a considerable amount of close office work. The principal sanatoria recommended are Aliwal North, at an elevation of 3,000 feet, Cradock (3,000 feet), and Bloemfontein (5,000 feet), all well situated, and enjoying a dry soil, abundant sunshine, and a clear exhilarating atmosphere. At the latter place, the capital of the Orange Tree State, a certain amount of civilisation prevails, and comforts are to be had, with the prospect of a sanatorium being established for consumptives. Many of these might object to the somewhat rough journey from the coast in remarkable vehicles called Cobb's coaches, or in tent-waggons; but our author assures us that even the weaker invalids reap benefit from travelling slowly in a bullock-wagon for days together, and sleeping in it at night. Thus open air by night and day in this exhilarating climate is insured. Pleuropneumonia has prevailed lately among the Dordrecht cattle, and Dr. Ross gives an account of the practice of inoculation in vogue. 'The diseased lung of a dead animal is placed in a vessel, and tapes are immersed in the liquid draining from it. These are passed through the tails of the young cattle; severe inflammation sets in, and the tails occasionally drop off. Thus was explained the Manx-cat-like appearance of many of the oxen.' As we said before, the author's experiences of Africa (especially of the ostrich farms) are entertaining, and far preferable to his opinions on the climate question generally. He tries to build too much on the phthisis death-rates of the British army in different colonies, and contends that it is a fair inference that a climate that does not favour the development of phthisis will exercise a favourable influence on the already phthisical patient, a conclusion by no means proved, and opposed to Dr. Ross's own evidence about the Cape sanatoria. Also change of climate is only advised for cases of non-tubercular phthisis, the author alluding to Niemeyer's opinion, that, if a consumptive patient is known to have tubercles, he had better not be sent away from home, but die there in peace among his friends. We question, after the debate on tubercle at

the Pathological Society, whether anybody is prepared to closely distinguish between tubercular and non-tubercular cases; and we are prepared to affirm that in by far the majority of *post mortem* examinations of cases of phthisis tubercle is detected, as a reference to the records of any large consumption hospital will show. Such being the case, surely it would be unwise to debar the greater number of consumptives from the benefits of climate, because they are suspected of tubercle, though it may be a limited amount, and likely to remain dormant for years. Dr. Ross's book contains some good references, and is on the whole very readable.

C. THEODORE WILLIAMS, M.D.

NEW INVENTIONS.

TIDMAN'S SEA-SALT.

This preparation, which has now been before the public for some years, has so well stood the tests of time and trial, that it fairly deserves the recommendation of the medical profession as a really valuable adjunct to the daily bath. It is frequently found that many persons object to the use of the bath from the fact that they do not get sufficient ensuing reaction, and consequently feel chilly for some time after using it. Personal experience warrants us in saying that this unpleasant and unhealthy symptom is entirely removed by the use of Tidman's sea-salt, dissolved in the cold or tepid water which is to form the bath; followed by brisk friction with a brush or rough towel.

The salt excites the action of the skin, and a pleasant glow is the unfailing result of its use. The free action of the pores thus obtained is of great value in the hygienic treatment of many forms of indigestion, debility, and other diseases, due to imperfect action of the skin.

MISCELLANY.

THE number of students registered in the Paris Faculty of Medicine this year is 6,500, the largest number yet reached. On February 22, the Municipal Council of Paris voted a sum of six millions of francs for the construction of new buildings round the old ones belonging to the Faculty. The property of the buildings now in existence has been given up by the State to the city of Paris, on the express condition that they should always be devoted to the Faculty of Medicine.

MEDICAL ADVERTISING IN CENTRAL AFRICA.—Lieutenant Cameron in the course of his description of his journey across Africa, delivered at the Royal Geographical Institution, told his audience that having at last reached the shore of the lakes, he had the opportunity of seeing a sort of congress of native doctors, who went about each with a row of iron bells hung over his loins, which he kept perpetually ringing to attract patients. With a sly touch of satire, the explorer remarks that, like doctors elsewhere, those eminent physicians were very solicitous about their fees.

INFANT MORTALITY IN EGYPT.—The following passage is extracted from an article in the *Times* on the Egyptian Fellahen. The author says, 'The philosopher who deemed him happiest who has the fewest wants ought to have been an Egyptian fellah. He is sometimes even born in the fields. The women work up to the day of their confinement. They lie up one day, and are out again the next, and the baby is laid near them in the fields on a bit of sacking. Ignorance and poverty lead to other sad consequences. Premature old age comes on at 40, and the population is kept down by a terrible infant mortality. Out of the 140,000 annual deaths, 80,000 are of infant children. It has been calculated that three out of every five that are born die before the age of two. For those that survive, an old Egyptian custom that is still practised is most symbolical of their future. The child is put into a sieve and rolled about to the beating of drums. "It is in order to harden him," say the people.'

INTEMPERANCE AND DIPSO MANIA AS RELATED TO INSANITY.—Dr. Edward C. Mann, Medical Superintendent of the State Emigrant Insane Asylum, Ward's Island, New York, in an article bearing the above title, published in the current number of the *Journal of Psychological Medicine* gives it as his opinion, that it is impossible to estimate the complex influences exerted by intemperance upon the production of insanity. Many superintendents of foreign asylums have estimated the admissions from intemperance at twenty-five per cent. or higher, including not only the proximate, but the remote cause of the disease. Dr. Mann states that he has traced intemperance as a cause in almost every case of general paralysis that has fallen under his notice, and that others have observed the same thing. M. Lunier estimates that fifty per cent. of all the idiots and imbeciles to be found in the large cities of Europe have had parents who were notorious drunkards. Out of 350 insane patients admitted during two years at Charenton, insanity was attributed to drink in 102 instances. Dr. Mann arrives at the conclusion from his examination of the statistics of all the insane asylums both here and in Europe, that it is not too much to say that fully one fourth of all the admissions are due either proximately or remotely to intemperance.

EFFECT OF EXTREME COLD ON MIND AND BODY.—M. Payer, the eminent Arctic explorer, referring to a certain day on which the thermometer indicated 58° Fahr. below zero, says that so great an amount of cold paralyses the will, and that, under its influence, men, from the unsteadiness of their gait, their stammering talk, and the slowness of their mental operations, seem as if they were intoxicated. Another effect of such cold, mentioned by M. Payer, is a tormenting thirst, which is due to the evaporation of the moisture of the body. It is unwholesome, too, to use snow to quench the thirst, as it brings on inflammation of the throat, palate, and tongue; besides, a temperature of 35½° to 58° Fahr. below zero makes it taste like molten metal. Snow-eaters in the North are considered as feeble and effeminate, in the same way as is an opium-eater in the East.

THE MEDICAL CONGRESS AT SEVILLE.—The *Cronica Oftalmologica* contains an account of the late Medical Congress at Seville; the first meeting of the kind which has ever been held in Spain. The most remarkable papers read were on the mineral waters of Andalusia, and their application to the treatment of skin-diseases; on pulmonary phthisis in Andalusia; on hæmatozoa as indications of certain pathological conditions; on the nature and treatment of puerperal fever; on renal and vesical calculi; on subperiosteal resections of the upper extremities; on cancer; on acupuncture as a means for the diagnosis and treatment of diseases of the mammary gland; on septicæmia; on the treatment of lachrymal fistulæ by cauterisation of the sac; and remarks on scurvy and alcohol dressings. The number and variety of the subjects treated must have given interest to this first gathering of our Spanish professional brethren, and is of hopeful augury for the congress to be held at Granada next year.

THE JOHN HOPKINS UNIVERSITY.—The inauguration of the John Hopkins University, Baltimore, took place on February 23; a large assemblage was present, including many visitors from the universities of America. The salutatory address was delivered by President Eliot, of Harvard University, whose finished oratory and beautiful writing were decidedly the event of the day. President Gilman responded in a long address, explaining the plans to be adopted in the organisation of the different departments. It is proposed to follow, to a certain extent, the German University system, borrowing some ideas from the French also. With reference to the sciences of medicine and biology, he thought that it was imperative that some vigorous steps be taken, in consideration of the facts that provisions in America for medical instruction cannot compare with those of European universities; that the medical schools have been inadequately endowed; that the system of fees for tuition has led to great abuses; that in some of the best colleges the degree of doctor of medicine can be won in half the time required for the degree of bachelor of arts; that there is a disposition to treat American diplomas as blank paper by civilians at home and by the professions abroad; that ignorance and quackery vaunting diplomas are prevalent, and that medical degrees conferred by a bogus university are openly sold like patent pills. Then, turning to the other side of the picture, when we see what admirable teachers have given instruction among us in medicine and surgery, what noble hospitals have been erected, what marvellous discoveries in surgery have been made by our countrymen, what ingenious instruments they have contrived, what humane and skillful appliances they have provided on the battle-field, what measures are in progress for advance in hygiene and the promotion of public health; when we see what success has attended recent efforts to reform the system of medical education, we need not fear that the day is far distant. We may rather rejoice that the morning has dawned which shall see endowments for medical science as munificent as those now provided for any branch of learning, and schools as good as those which exist in any other land. It will doubtless

be some time after the opening of the University before the opening of the hospital, and this interval may be spent in forming plans for the department of medicine. President Gilman urged the importance of instruction antecedent to the study of medicine; such instruction is avoided by students ordinarily, as a glance at the catalogue will prove. He advocated a course similar to that begun at the Sheffield School, New Haven, but more extended. Such a course should include abundant practice in the laboratories of chemistry, zoology, and physics; the study of anatomy, physiology, and palæontology, and of the lower forms of life; the investigation of the principles of drainage and ventilation, and of climatic or meteorological laws; the geography of diseases, with the remedial agencies of nature. President Gilman advocated such facilities as are now afforded, for instance, by Huxley in London, Rolleston at Oxford, Foster at Cambridge, Leukart, Kolbe, and His at Leipzig, Hoffmann and Reichert at Berlin. It is proposed to make the medical department independent of students' fees, thus avoiding the temptation to bestow diplomas upon unworthy candidates. The fund is ample for this, nearly eight millions being bequeathed, to be distributed as follows, 3,500,000 dols. for the University, 3,500,000 dols. for the hospital, and the balance to local institutions of education and charity.

ROYAL INSTITUTION.—The annual meeting of the members of the Royal Institution took place on May 1, Mr. George Busk, F.R.C.S., F.R.S., in the absence of the President, the Duke of Northumberland, D.C.L., in the chair. The annual report of the Committee of Visitors testified to the continued prosperity and efficient management of the institution during the past year. Fifty-six new members had been elected, and sixty-one lectures and nineteen evening discourses had been delivered. The library had so far grown that 323 volumes, exclusive of periodicals, had been added, about one-half having been presented to the institution. Thanks were voted to the president, treasurer, secretary, the committees of managers and visitors, and the professors for their services during the past year, a special compliment being paid to Dr. Spottiswoode, the secretary, for his gratuitous course of four lectures on 'Polarised Light,' in March and April last. The election of officers for the present year was then proceeded with, after which the chairman, in the name of the members of the institution, presented a silver salver, and a purse containing 300 guineas, to Professor Tyndall, F.R.S., as a congratulatory testimonial *à propos* of his recent marriage. In returning thanks, the professor said he hoped the members would, at a future time, allow him to 'render an account' of the way in which he disposed of the money portion of the testimonial. In connection with the institution, and also in other directions, he had devoted his energies to the acquisition and diffusion of scientific knowledge, and incidentally to these labours his income had increased sufficiently for his personal requirements, and he therefore trusted that he should be left at liberty to expend the sum alluded to in such a manner as he hoped would meet with the approbation of the kind donors. There had been, he went on to say, a time when the diffusion of science among the people of England depended almost entirely upon individual effort, and though Government had since generously come forward with its aid, it was not upon State efforts that we had to place our main dependence so much as upon the sound steady work of institutions like their own. We had, it was true, in this country vastly fewer scientific educational institutions than existed in France and Germany. He felt, nevertheless, that the educational problem would eventually be more effectually solved in England than in any other country upon the earth. He would not detain the meeting further than to once more tender his earnest and hearty thanks for the very generous conduct shown towards him.

LEPROSY.—According to Dr. Vandyke Carter's lately published reports on Leprosy, it appears that it is a disease of a slowly contagious character and naturally of very pro-

tracted duration, lasting from eight or nine to fifteen or twenty years, and that it is chiefly prevalent among the poorer classes, and especially among such as subsist upon scanty or unwholesome food. In many of its forms it reveals itself by some disfigurement of the features, so that it is readily recognised by ordinary observers, and its slow progress is attended by loathsome sores and by loss of the fingers and toes, which gradually perish and drop off. As in Judæa, it is the custom of the country—at least, among the poor, who furnish the great majority of the cases—to expel lepers from their homes and from society as soon as the nature of their complaint is discovered, and to look upon it as a valid ground for the disruption of all domestic ties. The husband drives away his wife, or the father his children, and takes no further thought for their welfare or subsistence. They become outcasts, exposed to all inclemencies of weather and to all extremities of want, and supported, if such a word can be used, by food or money which is exposed for them by the charitable, and which they may only take after the giver has departed, or by such roots and natural produce as they can obtain for themselves in the jungles. In Bombay there are two establishments into which lepers are received—one of them the Dhurmsala, named after the late Sir Jamsetjee Jeejeebhoy; the other the ward for incurables which is attached to the Sir Jamsetjee Jeejeebhoy Hospital. The latter not only contains 30 male lepers, but provides them with proper hospital accommodation and careful medical treatment; while the Dhurmsala contains 120 lepers of both sexes, who are better off than they would be as wandering outcasts, but who are crowded together in defiance of all hygienic considerations. In order properly to estimate the relation between the evil and the provision thus made for its relief it must be remembered that the known lepers in the Bombay Presidency exceeded 11,000 in number in 1871, and that the number in the whole Indian peninsula is supposed to be not less than 100,000. Their condition may be fairly estimated from a narrative extracted from a letter in the *Times of India* for June 18. The writer says of a leper man whom he had lately seen: 'He was the servant of a Brahmin landowner in the Concan, and, while present at a marriage festival, was noticed to have some (leprous) thickening of the ears and face. Thereupon the people insisted on his leaving the village; his wife and child left him, and he took refuge in a reed hut once belonging to some wandering tribe of Katodies. At morn and even he ventured near the outlying dwellings to beg a little food. He ate such fruit as was procurable, and, possessing as his all the sum of eight annas, he expended that in buying from the young cowherds fragments of their meals. Finally, he left the locality and reached Bombay. Contrary to what is usual, this man was in fair bodily condition and able to work, but no one in Bombay would employ him.'

INTERNATIONAL MEDICAL CONGRESS, PHILADELPHIA, 1876.—The International Medical Congress will be formally opened at noon, on Monday, September 4, 1876, in the University of Pennsylvania. The following addresses will be delivered before the congress in general meeting:—Address on Medicine, by Austin Flint, M.D., Professor of Practice of Medicine in Bellevue Hospital Medical College, New York. Address on Hygiene and Preventive Medicine, by Henry I. Bowditch, M.D., President of State Board of Health of Massachusetts. Address on Surgery, by Paul F. Eve, M.D., Professor of Operative and Clinical Surgery in the University of Nashville. Address on Obstetrics, by Theophilus Parvin, M.D., Professor of Obstetrics in the College of Physicians and Surgeons of Indiana. Address on Medical Chemistry and Toxicology, by Theodore G. Wormley, M.D., Professor of Chemistry in Starling Medical College, Columbus, Ohio. Address on Medical Biography, by J. M. Toner, M.D., of Washington. Address by Dr. Hermann Lebert, Professor of Clinical Medicine in the University of Breslau. Address on Medical Education and Medical Institutions, by Nathan S. Davis, M.D., Professor of Principles and Practice of Medicine in Chicago Medical College. Address on Medical Literature,

by Lunsford P. Yandell, M.D., late Professor of Physiology in the University of Louisville. Address on Mental Hygiene, by John P. Gray, M.D., Superintendent and Physician to the New York State Lunatic Asylum, Utica, New York. Address on Medical Jurisprudence, by Stanford E. Chaillé, M.D., Professor of Physiology and Pathological Anatomy in the University of Louisiana.

Discussions on scientific subjects will be opened in the sections as follows:—*Section I. Medicine.*—1. Typhomalarial Fever; is it a Special Type of Fever? Reporter, J. J. Woodward, M.D., Assistant-Surgeon U.S. Army. 2. Are Diphtheritic and Pseudo-membranous Croup Identical or Distinct Affections? Reporter, J. Lewis Smith, M.D., Physician to the New York Infants' Hospital. 3. Do the Conditions of Modern Life favour specially the Development of Nervous Diseases? Gentlemen intending to make communications upon scientific subjects, or to participate in any of the debates, will please notify the Commission before August 1, in order that places may be assigned them on the programme.

In order to facilitate debate there will be published on or about June 1 the outlines of the opening remarks by the several reporters. Copies may be obtained on application to the corresponding secretaries. The volume of transactions will be published as soon as practicable after the adjournment of the Congress. The public dinner of the Congress will be given on Thursday, September 7, at 6.30 P.M. The registration book will be open daily from August 31, from 12 to 3 P.M., in the Hall of the College of Physicians, N.E. corner 13th and Locust Streets. Credentials must in every case be presented. The registration fee (which will not be required from foreign members) has been fixed at ten dollars, and will entitle the member to a copy of the transactions of the Congress. Gentlemen attending the Congress can have their correspondence directed to the care of the College of Physicians of Philadelphia, N.E. corner of Locust and Thirteenth Streets, Philadelphia, Pennsylvania. There is every reason to believe that there will be ample hotel accommodation, at reasonable rates, for all strangers visiting Philadelphia in 1876. Further information may be obtained by addressing the corresponding secretaries. All communications must be addressed to the appropriate secretaries at Philadelphia. The foregoing programme is published by the authority of the Committee of Arrangements of the Centennial Medical Commission. S. D. Gross, President, William B. Atkinson, M.D., 1400, Pine Street, Recording Secretary, William Goodell, M.D., 20th and Hamilton Streets, and Daniel G. Brinton, M.D., 115 S. 7th Street, American Corresponding Secretaries, Richard J. Dunglison, M.D., 814 N. 16th Street, and R. M. Bertolet, 113 S. Broad Street, Foreign Corresponding Secretaries.

The London Medical Record.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

STRICKER, RIESS, BROADBENT, MACLAGAN, AND OTHERS ON THE USE OF SALICYLIC ACID AND SALICIN IN ACUTE RHEUMATISM.

Among the results obtained from the internal use of salicylic acid, its effects not only as an antipyretic but almost—if the statements already made be supported by further observations—as a curative, in rheumatic fever, are most noteworthy. Several articles on the subject have recently appeared in the German and other periodicals, from which we make the following quotations.

Dr. Stricker writes (*Berliner Klinische Wochenschrift*, nos. 1 and 2, 1876) as follows. For several months, all the cases of acute articular rheumatism in Professor Traube's wards have been treated with salicylic acid. In all the patients thus treated, not only has there been arrest of the increase of temperature within forty-eight hours, generally much sooner, but they have been freed from the local symptoms—swelling, redness, and tenderness of the joints. He regards salicylic acid, apart from its antipyretic action, as the most active, perhaps as a radical, remedy in acute articular rheumatism. He insists on the use of pure salicylic acid, which is in the form of white glistening needles, tasteless, and perfectly soluble in water and alcohol. The irritant action on the mucous membrane of the mouth, œsophagus, and stomach, appears to be due to impurities. Pure salicylic acid can be given in rather large doses without producing any troublesome effects of the kind on the mouth and pharynx, even though it gives rise to dryness of the mucous membrane, followed by slight burning and by increased secretion. He gave pure salicylic acid in hourly doses of $7\frac{1}{2}$ to 15 grains in a wafer, washed down with water like a pill. The doses were continued until the previously affected joints could be moved without pain. To attain this end, sometimes larger, sometimes smaller quantities were required; never more than 15 grammes or less than 5 grammes (225 grains and 75 grains). The only general symptoms produced were diaphoresis, noises in the ears, and difficulty of hearing; in two cases there was abnormal cheerfulness. Sufficient data do not yet exist for determining the action of salicylic acid in arresting or preventing cardiac disease.

Dr. Stricker's observations are based on peculiar cases, of which he relates two under the following headings: 1. Rheumatic polyarthritis; third attack; insufficiency of the aortic valves; complete arrest of the disease in twenty-four hours. 2. Rheumatic polyarthritis; cure within forty-eight hours; recent endocarditis on admission, which remained uninfluenced by the treatment, and led to slight mitral insufficiency; pericarditis, commencing when

the treatment was begun, disappeared under the continued use of salicylic acid. 3. Rheumatic polyarthritis running a slow course, with slight rise of temperature. When the patient was in hospital, rapid swelling and pain of several of the large joints, with increase of local temperature. Cure within forty-eight hours. 4. Rheumatic polyarthritis; strongly marked local affection; cured within twenty-four hours. 5. Rheumatic polyarthritis; two attacks; the first subdued in forty-eight, the other within twenty-four hours.

Riess contributes to the *Berliner Klinische Wochenschrift* (no. 7, 1876) an article on the use of salicylic acid, especially in acute articular rheumatism. He gave it in twenty-seven cases in the Berlin General Hospital; in the first twenty-three as an antipyretic when the temperature reached 102° Fahr. The antipyretic action was almost always very good; the lowering of temperature often lasting a day or even longer. The following were the numbers of doses required to produce complete reduction of the pain:—in six cases, 1 dose; in five cases, 2 doses; in two, 3 doses; in one, 4 doses; in two, 5 doses; in one, 6 doses; in four, 8 doses; in one, 15 doses; and in one, 20 doses. The fall of temperature was usually soon followed by relief of the affection of the joints and general improvement; but this was more constant in the earlier cases. After an improvement for one or nine days, a return of the joint affection with or without increase of temperature was often observed. The time required for complete cure—i.e. removal of the pain, swelling, and stiffness of the joints—was in one case three days; in two, four days; in two, six days; in two, seven days; in two, eight days; in one, eleven days; in one, thirteen days; in two, fourteen days; in one, fifteen days; in two, six weeks; in one, seven weeks; in two, two months; in four, more than two months. Of the last four cases, two were protracted by tedious complications—pericarditis in one, and periostitis of the femur in the other. With the exception of slight endocarditis in some, the remaining cases were uncomplicated.

Riess has lately used, in six cases, salicylic acid in small doses (not exceeding fifteen grammes) in solution of phosphate of soda, as recommended by Stricker. Two of the patients had been already treated by salicylic acid in large doses, but suffered from obstinate relapses, principally in the form of pains and stiffness of the joints. One of the patients took 165 grains of salicylic acid in solution of phosphate of soda in a day and a-half; the other took $4\frac{1}{2}$ drachms in the same way in two days, the doses being given every one or two hours. In both the pains were relieved, but returned when the medicine was discontinued. Of the other four cases, a very favourable result was obtained in one only, and in none of these was any effect produced on the duration of the disease. The disappearance of the symptomatic fever was, however, constant. In one of the four cases, the local symptoms disappeared in three days; in the others, it remained unaffected, although the medicine was given in large doses.

Riess says that in several necropsies of patients to whom salicylic acid had been given in substance, he found traces of its action on the mucous membrane of the œsophagus, stomach, and intestine.

While he points out the great difficulty of arriving at results in the treatment of acute articular rheumatism, he comes to the conclusion that neither his own cases nor those related by Stricker prove that

salicylic acid is a certain remedy in this disease. He formulates his opinion as follows. Salicylic acid acts as an excellent antipyretic in acute articular rheumatism; the reduction of temperature produced by its administration is generally attended with relief of the joint-affection, and it appears that in favourable cases, which come early under treatment, the duration of the disease may be cut short.

Besides the mixture of salicylic acid with solution of phosphate of soda, Riess has used commercial salicylate of soda. A full dose of this is ninety grains (equal to about seventy-five grains of salicylic acid); it is best given in the following form: salicylate of soda, six parts; distilled water, twenty parts; liquorice juice, five parts. This solution is readily taken, and is rarely followed by vomiting.

In a second article on the same subject (*Berliner Klinische Wochenschrift*, February 21, 1876). Dr. Stricker replies to some criticisms by Riess, and formulates the conclusions at which he has arrived in the following words. 1. Salicylic acid appears to be a rapid and radical remedy in recent cases of genuine acute rheumatism of the joints. 2. It is not injurious to the human organism when administered every hour in doses varying from $7\frac{1}{2}$ to 15 grains. 3. It can be given in these doses for a longer time to young and strong individuals than to the old and feeble. 4. In the latter, it produces toxic symptoms more readily than in the former. 5. The toxic symptoms vary in degree. 6. Those most commonly met with are noises in the ears, difficulty of hearing, and diaphoresis; when these occur, the administration of the medicine should be discontinued. 7. If salicylic acid be found to fully answer the expectations entertained regarding it, the internal administration of a certain quantity may be expected to prevent the occurrence of fresh attacks in hitherto unaffected joints, and also secondary inflammation of serous membranes, especially the endocardium. 8. To prevent relapse, the medicine must be continued in smaller doses for some days after the termination of the main treatment. 9. Salicylic acid is of doubtful utility in chronic articular rheumatism. 10. It is not likely to be of use in gonorrhœal or diarrhœal rheumatism, or in the polyarthritis attending septicæmia.

Dr. Katz describes, in no. 4 of the *Deutsche Medicinische Wochenschrift*, a case of acute articular rheumatism successfully treated with salicylic acid. The patient was a man, in whom the fingers, wrists, shoulders, and knees were affected. Nitrate of potash, quinine, and morphia were given for ten days without relief. There was much pain and swelling; the temperature was 102° to 103° Fahr., the pulse 100 to 120. The administration of salicylic acid, in 15 grain doses hourly, was commenced on the tenth evening; and the next morning, a drachm having been taken, he was able to move both his hands freely, and even to move out of bed, neither of which he could do on the previous day. The medicine was continued. In the evening there was no fever, the pulse was 90, the respiration free; motion was not painful, and there was no swelling of the parts. Forty-eight hours after the commencement of the treatment by salicylic acid he was out of bed, and could walk without assistance.

Dr. Hildebrandt describes (*Deutsche Medicinische Wochenschrift*, no. 7, 1876) a case of acute rheumatism in a girl aged eleven. From January 24 to 28 she had circumscribed peritonitis on the right

side, which disappeared under the use of opiates and the application of bladders of ice. On the 31st, when Dr. Hildebrandt visited her, the temperature had risen to 97.9° ; she could not open her mouth, and complained of pains in the ear; she could not move her arms, and movements of the left hip-joint caused severe pain. Pressure under the lower jaw was painful; the elbows were slightly swollen, but not red, and movement of them gave great pain. Nothing abnormal was found on examination of the heart. About four grains of salicylic acid were ordered to be taken every hour in fennel-water. At 11 A.M. next day there was a considerable improvement in all the symptoms. The next night she slept well, and awoke next morning free from pain and fever. The salicylic acid was continued three times a day, in doses of one decigramme ($1\frac{1}{2}$ grain).

Dr. Steinitz, of Dresden (*Allgemeine Medicin. Central-Zeitung*, March 4, 1876), has given salicylic acid in several cases of acute articular rheumatism with success. He administers the pure acid in wafers or capsules, or in water, in doses of half a gramme ($7\frac{1}{2}$ grains) every hour. He has also used it in several cases of chronic articular rheumatism, but without effect.

Cases demonstrating the successful use of salicylic acid in acute rheumatism are also described by Dr. Teuffell (*Württemberg Med. Correspond.-Blatt*, no. 5, 1876); Dr. Putnam (*Boston Medical and Surgical Journal*, February 24); and others.

In the *Lancet* for April 8 is an account of four cases of acute rheumatism, two being of more than average severity, treated in St. Mary's Hospital, by Dr. Broadbent, with salicylic acid. The dose given in the first case was $7\frac{1}{2}$ grains; in the second, fifteen grains; and in the third and fourth twenty grains. It was administered every hour in these doses for six hours. In all the cases the result was a rapid reduction of the temperature, and an early relief of the patients from the local symptoms. In commenting on the cases, Dr. Broadbent says: 'It was impossible not to be astonished with the effects, and notwithstanding the many disillusion experiences in medicine brings, not a few of which have been furnished by acute rheumatism, I should not do justice to my conviction were I not to say that apparently we have in salicylic acid a remedy for rheumatic fever comparable to quinine as a remedy for ague. According to present experience rheumatic fever when treated by this drug is an affair of two or three days. The disease is common enough, and its usual course sufficiently well known, so that no long time will be required to establish some definite conclusion, and to bring out any possible injurious effects. The only complaint hitherto made of the acid is that it is hot and irritating to the throat; given in milk vomiting has been produced.'

'Careful examination of the effects on the pulse, temperature, urine, etc., will no doubt yield important information. Mr. Sworder, who has watched the cases very closely, states that the temperature invariably rises for a short time after the administration of the first dose, but the observations recorded in the careful notes taken at short intervals by him and Mr. Gawith, show a gradual fall, both of temperature and pulse-rate. No sphygmographic observations were made. Relief from pain was always quickly obtained, and, as a rule, the patients slept well, no opiate being required; as a rule, again, there was very free perspiration, but this of course is common in acute rheumatism.'

A paper by Dr. T. Maclagan, of Dundee, in the *Lancet* for March 4 and 11, on the treatment of acute rheumatism by salicin, must be mentioned in connection with the subject now under notice. Dr. Maclagan, holding the opinion that rheumatic fever is of malarious origin, was led to employ salicin, which has long enjoyed a reputation for tonic and febrifuge properties, and was at one time a good deal used as a substitute for quinine. He says: 'The idea of treating acute rheumatism by salicin occurred to me in November, 1874. I had at the time under my care a well-marked case of the disease, which was being treated by alkalies, but was not improving. I determined to give salicin; but before doing so, took myself first five, then ten, and then thirty grains, without experiencing the least inconvenience or discomfort. Satisfied as to the safety of its administration, I gave to the patient referred to, twelve grains every three hours. The result exceeded my most sanguine expectations. For some days prior to its administration the temperature had ranged from $101^{\circ}8'$ to 103° ; the pulse was 120, and the joints were swollen and very painful. On November 26 the alkaline treatment was stopped, and that by salicin commenced. On the following day, after eighty-four grains of salicin had been taken, the pulse had gone down to 100, the temperature to $99^{\circ}6'$ (from $102^{\circ}8'$ the previous day), a fall of over 3° , the pain and swelling of joints, but especially the pain, had much abated, the joints could be moved a little, and the patient expressed himself as being much better. On the next day (November 28) the temperature was natural, and the pain all but gone, the joints still remaining stiff. From this time he convalesced steadily and quickly.

'The case was a very striking one; but, by itself, could not be regarded as proof of the beneficial action of salicin. I was quite aware that cases of acute rheumatism do sometimes unexpectedly improve without any treatment, and had no surety that this was not a case in point. It afforded me, however, strong encouragement to persevere with the salicin. This I did; and all the cases of acute and subacute, and several of the cases of chronic, rheumatism, which have come under my care since then, have been treated by this remedy, and with results much more satisfactory than I ever got from any other remedy, the results being most marked and most satisfactory in distinctly acute cases, and least so in chronic cases.'

He gives the details of eight cases; four acute, three subacute, and one chronic. The following are the conclusions at which he arrives.

1. We have in salicin a valuable remedy in the treatment of acute rheumatism.
2. The more acute the case, the more marked the benefit produced.
3. In acute cases, its beneficial action is generally apparent within twenty-four, always within forty-eight, hours of its administration in sufficient time.
4. Given thus at the commencement of the attack, it seems sometimes to arrest the course of the malady as effectively as quinine cures an ague or ipecacuanha a dysentery.
5. The relief of pain is always one of the earliest effects produced.
6. In acute cases, relief of pain and a fall of temperature generally occur simultaneously.
7. In subacute cases, the pain is sometimes decidedly relieved before the temperature begins to fall; this is especially the case where, as is frequently observed in those of nervous temperament, the pain is proportionately greater than the abnormal rise of temperature.

8. In chronic rheumatism, salicin sometimes does good where other remedies fail, but it also sometimes fails where others do good.

Regarding the action of salicin on the cardiac complications of rheumatic fever, Dr. Maclagan has no experience. But, he observes, a remedy which curtails the duration, or mitigates the severity, of an attack of rheumatic fever, must of necessity diminish in a proportionate degree the risk of cardiac mischief.

The dose of salicin is from ten to thirty grains every two, three, or four hours, according to the severity of the case. Fifteen grains every three hours is a medium dose for an acute case. It is very certain that a much larger dose may be given without producing discomfort. Salicin is not soluble to any useful extent; it is best administered as a powder mixed with a little cold water. It is a very pleasant bitter. Dr. Maclagan never found the least inconvenience follow its use.

Dr. Maclagan further says that when salicylic acid (originally prepared from salicin) was first introduced, he determined to try it; and in the one case in which he did have recourse to it, it seemed to do good to the rheumatism; but it caused so much irritation of the throat and stomach that he did not repeat it. This was, no doubt, due to its being impure. He has no doubt that Traube's (Stricker's) observations are correct, and that salicylic acid will be found efficacious in the treatment of acute rheumatism. But he has as little doubt that it is not so good as salicin for this purpose, for it is more apt to contain noxious impurities, it is not so pleasant to take, and it apparently requires a larger dose to produce its beneficial action.

In the *Centralblatt für die Medicinischen Wissenschaften* for April 1, Dr. Senator, of Berlin, referring to Dr. Maclagan's paper, disputes the correctness of his idea that rheumatic fever is of malarial origin. Quinine itself, he says, is very uncertain in its effect in cases of rheumatism. He has also made observations on the therapeutic action of salicin, and has found results similar to those described by Dr. Maclagan. He believes, however, that the effect is due to the conversion of most or the whole of the salicin into salicylic acid within the body.

He says that salicin, given in doses varying from 30 to 75 or 90 grains, reduces febrile temperatures as certainly as does salicylic acid. He has as yet not had an opportunity of giving it in acute rheumatism. It is free from the disagreeable effects sometimes attending the use of salicylic acid, and may be given in powder with sugar, in wafers, or in solution.

ON SUNSTROKE. BY SIR JOSEPH FAYRER, K.C.S.I., M.D.*

Synonyms.—Coup de Soleil; Insolatio; Ictus solis; Erythismus tropicus; Sun-fever; Heat-fever (G. B. Wood); Thermic-fever (H. C. Wood); Heat-apoplexy; Heat-asphyxia; Calenture; Loo-marna (hot-wind stroke, Hindostan).

Definition.—Certain pathological conditions resulting from exposure to solar or artificial heat. These conditions are:

1. Exhaustion and failure of the heart's action in syncope.

2. A condition like shock, in which from the direct action of heat on the brain and cord in exposure to

* From the *Practitioner*, March, 1876.

the sun's rays, the nerve-centres, and especially the respiratory, are influenced, causing rapid failure of the respiration and circulation.

3. Intense pyrexia due to vaso-motor paralysis, and to the nerve-centres being over-stimulated and then exhausted by the action of heat on the body generally. Failure of respiration, of circulation, and of innervation generally result, and asphyxia follows. Recovery is frequent, but in many cases is incomplete from structural changes having taken place in the nerve-centres.

Nature, Pathology, and Symptoms.—(a) Simple exhaustion and syncope may occur under great fatigue or over-exertion, or depression from any cause, during exposure to a high temperature. Or when the head and neck are exposed to an intense heat and sun-light, a condition analogous to shock may be induced, by reflex action through the vagus and vaso-motor system. There is depression of nerve force, and prostration of muscular power; the skin is pale, cold, and moist, the pulse quick and feeble. Death may occur rapidly in the state of collapse from failure of the heart. Complete recovery is frequent.

(b) Asphyxia and apnoea may come on very rapidly, after certain premonitory symptoms of depression and weakness, though occasionally without prodromata during exposure, especially of the head and spine, to the direct rays of a powerful sun, when the atmosphere is much heated, and the nervous energy has been depressed by over-fatigue, dissipation, or illness. The brain and nerve-centres, especially the respiratory, are overwhelmed by the sudden elevation of temperature; respiration and circulation fail, the failure of the latter being probably due to the inhibitory influence of the vagus. When death takes place, as it does sometimes, very suddenly, during great excitement or exertion, it has been attributed to rapid *ante mortem* coagulation of the cardiac myosin. This, however, though it may occur occasionally, is generally a *post mortem* change, the heart's action being brought to a close by the heat; in the same manner, as it has been shown by C. Bernard and Lauder Brunton, that the effect of high temperature on animals is first to accelerate and finally to stop the heart, and especially the ventricles, in a state of contraction. Recovery is frequently complete, but sometimes tedious, and in many cases imperfect, ending in serious impairment of health or intellect, indicative of structural changes caused in the nerve-centres. The symptoms of this form of insolation, the real *coup de soleil*, are those of sudden and violent injury to the nerve-centres—unconsciousness and cold skin, feeble pulse, all the symptoms of depression; death resulting from rapid failure of respiration and circulation. If not fatal, reaction may result in a variety of conditions indicative of the injury done to the cerebro-spinal system.

(c) An intense state of fever, the result of the influence of heat on the nerve-centres, and through them on the vaso-motor nerves, and of the heating of the body generally, by the direct action of either artificial or solar heat, may occur, quite independently of the immediate operation of the sun's rays. It comes on as frequently at night, or in the shade, as in the day or in the sunshine, especially in persons who are exhausted by fatigue, overcrowding, depression from any cause, such as dissipation, want of rest, present or recent illness, and notably when the atmosphere is impure from overcrowding or want of cubic space.

The temperature of the body rises to 108° or higher, 110°. The brain, medulla, and cord, the nerve-centres generally, and especially the respiratory, suffer from over-stimulation and then exhaustion.

Respiration and circulation fail; there are dyspnoea, hurried gasping breathing, great restlessness, thirst, fever, frequent micturition; the skin has a pungent, burning heat. Sometimes it is dry, sometimes it is moist. The pulse varies: in some it is full and laboured; in others quick and jerking; the face and head and neck are congested to lividity, and the carotid pulsations are visible; the pupils, contracted at first, may dilate widely before death; delirious convulsions and coma, frequently epileptiform in character, relaxation of the sphincter, and suppression of urine, come on, and are frequently the precursors of death, which is caused by asphyxia.

Recovery not unfrequently partially occurs, to be followed by relapse and death; or secondary consequences, the result of over-heating, end in meningitis or cerebral changes which may destroy life or intellect at a later period, or permanently compromise the whole health or that of some important function. The premonitory symptoms of this form of insolation often manifest themselves for some hours; it may be days before they culminate in the dangerous condition just described; general malaise, disordered alvine or other secretions, profuse and frequent micturition, restlessness, sleeplessness, apprehension of impending evil, hurried and shallow breathing, precordial anxiety, gasping, giddiness, headache, occasionally nausea or vomiting, thirst, anorexia, feverishness which soon amounts to a pungent heat of skin, and high temperature as shown by thermometer. The surface may be dry, but it is sometimes moist; the pulse varies; and these conditions gradually become aggravated, and frequently become worst at night, when the patient passes into the condition just described, and is found unconscious or dying.

The symptoms vary considerably, but they point to a profoundly disturbed state of the cerebro-spinal nerve-centres, and to pathological changes in the organs or structures whose functions have been so gravely disturbed. Death results from asphyxia and apnoea. Recovery is often incomplete, or followed by permanent impairment of health, and generally by complete intolerance of heat and exposure to the sun.

For the first of the conditions just described, the term heat-exhaustion; for the second, *coup de soleil*, or sunstroke; for the third, thermic fever or heat fever (Wood), seem the most appropriate designations; or, if all be included under one, the old term Calenture seems not unfitting.

The morbid conditions above described, being due to heat alone, are not peculiar to any country or climate, and are liable to occur wherever persons are exposed under any circumstances to great heat, whether solar or artificial. For example, soldiers marching or fighting when oppressed by weight of clothing and accoutrements are apt to suffer either from simple heat-exhaustion, or that form of insolation which results from direct action of the sun on the head and neck. This is common enough in India during the hot season, in other tropical countries, in America, and is not unknown in Europe, or even in England during the heat of summer. Soldiers, workmen, artificers, and others in factories, heated

rooms, hospitals, barracks, tents, and even ships, especially in hot climates, are liable to suffer from heat-exhaustion, which may pass into the dangerous condition of heat-fever or insolation.

The stokers, or men serving in the engine-rooms of steamers in the tropics—the Red Sea, for example—are not unfrequently brought on deck in a state of complete exhaustion, from which they generally recover when exposed to the reviving influence of the air, or to douches of cold water, with some stimulant if the syncope be prolonged. Soldiers or others in service when exposed to great heat may drop out of the ranks, fall suddenly, pass into a state of coma, and die immediately, or recover after being in the greatest danger, but with damaged constitutions, rendered unfit for further service or residence in a hot climate. These cases occur on exposure to the direct action of the sun's rays when the atmospheric temperature is high, and especially when unusual exertion is being made.

But the most frequent cases are those of heat-fever which come on in houses, barracks, tents, ships, by night or in the day, away from the direct solar rays. A form of disease sometimes described as ardent fever, in India, is this condition supervening on the ordinary phenomena of ephemeral fever. It seems pretty well understood that heat alone is the effective cause of the so-called sunstroke. Malarious and certain hygrometric or barometric states of the atmosphere, have no special influence beyond that which they may exert on the general vigour of the constitution, or in rendering that person more or less susceptible to heat, and so far predisposing him to suffer from it.

A dry air, such as that of North India, with hot winds, is much better tolerated at a high temperature, than the damp atmosphere of Bengal at a much lower one. The dry hot air favours evaporation, and thus keeps the body cool, while in the damp heavy atmosphere the natural cooling function is almost in abeyance. Vigorous healthy persons of moderately spare frame, possessing sound viscera, and leading temperate and regular lives, in an otherwise pure atmosphere, can tolerate a great amount of heat, and are much less liable to suffer from it than those in whom these conditions do not exist. Acclimatisation has also considerable influence in conferring toleration. New arrivals are more prone to suffer than those who have become accustomed to the climate. It is well known that the native can bear an amount of sun on his shorn head, neck, and half naked body with indifference if not pleasure, that would very soon prostrate a European. But to a temperature of the air rising above a certain standard, all succumb, and natives of India suffer like others and die in numbers every year from 'loo-marna' (hot-wind stroke).

The exact amount and duration of toleration of a high temperature depend, to a great extent, therefore, on the vigour of natural constitution and the present state of health. The natural refrigerating powers of the body when in health, are such as to enable men to support very high temperatures, much above that of the normal state of the body, 99°. Thus, in the hot dry winds no inconvenience beyond discomfort is felt, so long as transpiration and perspiration is free. This cools down the body, enabling it to resist the great heat. It is obvious that in this there is a great expenditure of force, and when it fails suffering soon ensues. Disordered health, dissipation, over-fatigue, anything, in fact, that de-

presses nerve-power, reduces the normal physiological capacity, and consequently renders a man more liable to succumb.

The mortality from sunstroke is about 45 to 50 per cent., but of those who recover many are permanently injured, and remain invalids for the remainder of life, which is often shortened by the changes induced. These may be some weakness due to obscure structural change in the cerebrum, or to a chronic form of meningitis which affects the sufferer in various degrees of intensity; epilepsy, impairment of memory, great nervous irritability, headache, insanity, partial paraplegia, partial or complete blindness, extreme intolerance of heat, especially of the sun's heat, rendering the person utterly incapable of serving or living in a hot climate, or of enduring exposure to the sun. Or it may gradually end in complete fatuity, insanity, or epilepsy, meningitis, which accounts for the intense cephalic pain, or in a lesser degree. disordered innervation and derangement of the functions generally, thus seriously comprising the general health.

Morbid Anatomy.—In cases where death has taken place suddenly, as from shock, there is no very remarkable appearance. The heart may be found firmly contracted, but not always so—it may be flaccid. The lungs and brain and membranes may be found somewhat congested, but not invariably. As in cases of shock, the venous trunks, especially those of the abdomen and the right side of the heart, may be found too full of blood, and the pulmonary vessels may be overloaded with blood. The blood itself is dark and gummy, and is found effused in patches of ecchymoses, and indeed rendering the body more or less livid; the coagulability of the blood is also impaired, and it is wanting in oxygen.

In death from ordinary cases of thermic fever, the lungs and pulmonary system are often deeply congested, the heart is firmly contracted from coagulation of myosin, the whole venous system is engorged, and the body even before death is marked by petechial patches, or extensive ecchymoses of a livid appearance.

The blood is generally more fluid and gummy than natural; its coagulability is impaired, and it is acid in reaction. The corpuscles, though generally presenting no abnormal change, are somewhat crenated, and have less tendency to form rouleaux than natural, and the quantity of oxygen is much diminished. The body for some time after death retains a high temperature; when first opened the viscera feel pungently hot, and the incisions drip dark blood. Rigor mortis comes on very rapidly, from early coagulation of myosin.

The brain and membranes may be found congested, and in some cases there may be evidence of meningitis. Serous effusions into the ventricles or hæmorrhage into the brain-substance may be found to have occurred, and are not improbable in the congested condition sometimes existing in the head; but the disease is asphyxia, not apoplexy, and the most important changes are found in connection with the thoracic viscera.

Treatment.—In cases of simple exhaustion ordinary treatment is all that is needed. Removal to a cooler locality, the cold douche (but not too much prolonged), or the administration of stimulants may be beneficial. Tight or oppressive clothing should be removed, and the patient treated as in syncope from other causes.

Rest and freedom from exposure to over-exertion, fatigue, or great heat should be enjoined.

In that form of sunstroke where the person is struck down suddenly by a hot sun, the patient should be removed into the shade, and the douche of cold water being allowed to fall in a stream on the head and body, from a pump (or, as in India, from the mussuck, or other similar contrivance) should be freely resorted to, the object being twofold: to reduce the temperature of the over-heated centres, and to rouse them into action. During the assault on the White House piquet in the last Burmese war, numbers of men were struck down by the direct action of the sun during the month of April. They were laid out perfectly unconscious, in their red coats and stocks (they wore them in those days, 1852), but were recovered by the cold douche freely applied by the mussuck over the head and body. In some cases rousing by flagellation with the sweeper's broom was added, and all recovered with the exception of two cases, both of which had been bled on the spot where they fell. Mustard plasters and purgative enemata may be useful.

If recovery is imperfect, and followed by any indication of injury to the nerve-centres, or by the supervention of meningitis, other treatment may be necessary according to the indications. Much exposure to the sun should be carefully guarded against, and unless recovery be complete and rapid, the sufferer should be removed to a cooler climate, the most perfect rest and tranquillity of mind and body enjoined, and the greatest care be observed in regard to extreme moderation in the use of stimulants.

In the cases of thermic fever, heat being the essential cause of the disease, the object is to reduce the temperature of the body as quickly as possible, and before tissue-changes have resulted from the action of heat. As the hyperpyrexia is due not only to the direct operation of heat on the nerve-centres and tissues, but to the fever set up by the disordered vaso-motor arrangements, remedies such as may influence this disturbed condition have been suggested. The results have appeared in some cases to justify the theory; and the hypodermic injection of morphia and of quinine have both been considered to produce good results by their influence on the vaso-motor nerves and their power in retarding tissue change.

Bleeding has now happily been almost abandoned. The congested livid surface, the coma and stertor, which formerly suggested it, are not now so treated. Bleeding has, no doubt, great power in reducing temperature, and there are cases in which it may still be practised with advantage; but they are, I think, the exception, and not the rule. In cases where venesection has appeared first to give relief and mitigate the symptoms, the improvement has been often transient and followed by relapse into a more dangerous condition, which has terminated fatally.

I could lay down no absolute rule in this or other diseases with reference to the abstraction of blood; and it is quite possible that greater immediate danger to life may exist in an over-distended right side of the heart than in the loss of an amount of blood that might have tided the patient over that state of peril; and therefore I would suggest that each case in this respect be treated according to its own peculiar merits. The treatment generally consists in the judicious applications of cold, either by

affusions or by the application of ice to the surface, the reduction of temperature being watched with a thermometer in the axilla, mouth, or rectum.

Care should be taken not to prolong the cold application too long, as danger arises from depressing the temperature below the normal standard. The bowels should be relieved, and blisters may be applied to the calvaria and neck, though I may say I have not much faith in their efficacy.

In the epileptiform convulsions that so frequently occur, the inhalation of chloroform or ether may be of benefit, but their administration must be carefully watched. The earliest and most severe symptoms having subsided, the febrile condition that follows is treated on ordinary principles—salines and aperients being given, but not to the extent of depressing the patient. The diet must be carefully regulated, and of the blandest and most nourishing nature.

As improvement progresses, other symptoms may supervene indicative of intracranial mischief. Where the indications are those of meningitis, the iodide of potassium and counter-irritants may be used with advantage. Removal to a cooler climate is essential; as a general rule, it is desirable that the sufferer should not, for a long period at least, return to a hot or tropical climate, and he should be guarded against all undue exposure to heat, work, or mental anxiety of any kind.

The sequelæ of sunstroke are frequently from such causes most distressing, and render the patient a source of anxiety and suffering to himself and to his friends.

The less severe symptoms—those, probably, indicative of the slighter forms of meningitis—or of abnormal brain or nerve change—occasionally pass away after protracted residence in a cold climate, but they are not unfrequently also the cause not only of much suffering but of shortening of life. It is not possible in a short notice to describe all the conditions that may result. They point to permanently disturbed, if not structurally injured, cerebro-spinal centres, and the treatment required is as varied as the symptoms presented.

CLINICAL LECTURES ON CEREBRAL SYPHILIS. BY PROF. H. C. WOOD.*

Delivered at the University Hospital, Philadelphia.

I. DIAGNOSIS.

Gentlemen,—The subject of syphilis of the nervous system is one of so much importance, on account of the frequency of its occurrence and of the practical results of its recognition and correct treatment, that I would to-day call your attention to it most especially.

Viewed from a pathological stand-point, and omitting affections of the cranial bones and their periosteum, cerebral syphilitic affections may be arranged in three classes: those in which the chief lesion is a neoplasm; those in which it is an inflammation; those in which it is a degeneration of the vessels. In a very large proportion of cases all three lesions co-exist, and probably, in the great majority of instances, at least two of them are present. That a tumour or a meningitis may be the sole expression of a syphilitic taint is well known; but the connection between degeneration of the cerebral vessels and syphilis is not so familiar.

* *Philadelphia Medical Times*, February 19, 1876.

The frequency with which the venereal taint leads to degeneration of the large arteries is now well established; and in the work of Dr. Heubner (*Der Luetische Erkrankung der Hirnarterien*, Leipsic, 1874) are collected various cases in which *post mortem* examinations have proven the invasion of the cerebral vessels by the constitutional infection. It seems to me very evident that the connection between apoplexy and syphilis is more frequent and more immediate than is usually believed. Most drunkards are dissipated in more ways than one, and upon every man or woman who has had impure connection rests the shadow of a possible syphilitic taint. Alcohol is assigned as the cause of capillary degeneration in very many fatal apoplexies occurring in the young. Probably syphilis rather than alcohol is in these cases often the *fons et origo mali*. Further, it is perfectly conceivable that these two causes shall be co-workers of ruin.

In hospital practice it is often difficult to learn the history of apoplexies; and I have not yet been able in any case of apoplexy to verify a syphilitic origin by the conjoint evidence of a history during life and the finding of specific lesions after death. In one in my wards in the Philadelphia Hospital, the existence of a syphilitic lesion of the vessels of the brain was made exceedingly probable during life by the co-existence of a slow progressive brain-failure, without evidence of localised cerebral disease, but with very numerous retinal apoplexies in both eyes; this patient passed out of view before a final result was worked out.

The *diagnosis* of cerebral syphilis is a threefold one, embracing the seat of the lesion, its character, and the question whether it is or is not specific. The important practical decision is always as to the nature of the lesion.

It makes some difference in the treatment whether we believe the departure from normal to be inflammatory or neoplastic; but this difference is slight when compared with the difference in the treatment of specific and non-specific cerebral lesions. This is the more satisfactory because, for reasons which I shall state presently, I am convinced that it is sometimes impossible in the present state of our knowledge to distinguish with certainty between the two lesions during life.

Given a case of evident brain-lesion, is it possible to decide as to its syphilitic nature from the symptoms? Theoretically, gentlemen, it is not possible; practically, we are often able to distinguish the specific nature with reasonable certainty. Evidences of a progressively increasing pressure at the base of the brain occurring in an otherwise healthy young or middle-aged adult, without a history of exposure to sun-stroke or other cause of meningitis, point strongly towards a syphilitic origin.

Non-specific basal meningitis and basal cerebral tumours are very rare in non-tuberculous adults. Upon this is dependent the fact that slowly developed paralyses of the motor nerves of the eye and its muscles are generally dependent upon syphilis. Paralysis of the portio dura of the seventh pair does not have a similar significance, for several reasons. The nerve arises so far back, and proceeds so immediately outwards to enter the internal auditory meatus, that it is not usually seriously compromised by a basal exudation, and therefore escapes in syphilitic meningitis. On the other hand, owing to its long passage through the bony canal, and to its extremely superficial and exposed point of exit, the facial nerve

is excessively apt to be paralysed by rheumatic or other inflammations and exudations. Hence, facial palsy may be said on the whole to be antisiphilitic in its expression. It must, however, be borne in mind that specific palsy of the nerve may occur. I have seen unquestionable cases of it.

Cerebral syphilis may, however, destroy a patient without the induction of basal exudation, and without producing a single suspicious symptom. In these cases the primary guide must be the history. Often this is very clear, but not rarely it is of such character as to obscure rather than reveal the truth.

Syphilis of the nervous system usually occurs very late in the disorder, and is in my experience especially prone to exist in those whose secondaries have been unusually light, or even—if there be any truth in man—have been absent. Patients very often having been free for years from specific disorders, having had families of healthy children, and, it may be, even unconscious that they have ever had a primary sore, are astounded when they learn the nature of their malady. I am inclined to believe that in most of these people, when stripped, the experienced eye would find some suspicious markings; but in this country you cannot strip men, still less women, on suspicion, and both men and women suffer from cerebral syphilis.

When to the facts enumerated is added the perverse tendency not rarely evinced by patients to deny stoutly, even to the peril of life, that which they know to be true, it is evident that too great care cannot be exercised in cross-examining a patient and in receiving his answers *cum grano salis*. In asking questions, be careful as to time and opportunity. I have seen the specific character overlooked because the doctor questioned the man before his wife. He would be a stern adherent to truth who did not break allegiance under such provocation. It has come to be my invariable rule always to believe that indications of meningitis or cerebral tumour occurring in an otherwise healthy young or middle-aged adult are the results of syphilis, if a confession be made of even a single impure connection in early life. Indeed, I will go further. Often it is well to avoid questioning your patient at all, for his sake, for his friends' sake, for your own sake. Leave the history of the past unstirred. Make the therapeutic test, and keep your own counsel. Nothing will be lost to the patient, and a few weeks will enable you to decide the matter. If, gentlemen, you do this in every case of brain-tumour or of chronic meningitis occurring in young or middle life, you will some time stumble most unexpectedly upon a brilliant result.

It is a matter of some practical, and always of much scientific, interest, to determine the exact character and seat of the lesion in cerebral syphilis. The rules which govern the judgment in deciding the seat of the lesion are the same for specific and non-specific cerebral disease, and I shall not speak of them here. In regard to the character of the lesion, the trouble is to distinguish between syphilitic meningitis and tumour.

You will remember that the symptoms present in cerebral syphilis are, failure of general intellection and of special intellectual functions, local and general paralyses, convulsions, headache, and changes in the optic disks. Let us take these symptoms up *seriatim*, and endeavour to determine, if possible, their diagnostic significance.

Failure of memory and of the general intellectual powers is common to both meningitis and tumour,

but is more usual and more intense in tumour than in meningitis. A complete or nearly complete loss of intellectual power occurring in a case of cerebral syphilis would certainly indicate a very wide-spread involvement of the brain-tissue—one which could scarcely be other than secondary to a tumour or to a degeneration of the cerebral vessels. Still, I have seen very pronounced loss of memory and slowness of intellect, when *post mortem* examination showed that the chief lesion was a general and intense meningitis. The destruction of local brain-functions, indicating organic lesion occurring at such positions as not to be affected by the exudation of meningitis, is very indicative of tumour. Even such loss of power, unless total, cannot, however, be relied on. Thus, in a case of very decided, though not complete aphasia, I found, on *post mortem* examination, meningitis without appreciable lesion of the island of Reil. Nevertheless, total abolition of a localised function must be considered as decisive of change affecting either the centre or its nerves, and, when present, affords the best criterion we have for deciding the nature of the lesion. Thus, a complete or even a nearly complete hemiplegia in cerebral syphilis is almost a complete proof of the existence of a profound alteration in the neighbourhood of the corpus striatum, and, hence, of tumour, or of brain-softening from capillary degeneration.

On the other hand, paralysis of the basal nerves of the brain indicates meningeal trouble, because a tumour, at least without co-existent meningitis, is very rare in such positions, whilst chronic meningitis habitually assaults, with its exudation, the nerves of this region.

The convulsions of cerebral syphilis are of two forms, the one indicative of meningitis, the other of tumour. In the meningeal form the convulsion, in all cases which I have seen, was evidently dependent upon an acute exacerbation, and was not truly epileptiform.

The convulsion does not pass in a few minutes, but continues for hours, is evidently excited by irritation, so as to be almost tetanic, and usually is accompanied by decided rigidity and opisthotonos. With it is not simply sleep or stupor, but wild delirium, a fury of screaming and fighting. True epileptiform convulsions occurring at irregular intervals in cerebral syphilis are indicative of tumour. I do not mean to affirm that they are positive proof of the existence of a tumour. The evidence upon this point is not sufficient. They certainly do render the existence of a tumour exceedingly probable. Fatal cases of cerebral syphilis, under proper treatment, are very rare. Wherever I have had an opportunity of making *post mortem* examinations where epilepsy has existed during life, a tumour was found after death.

I do not think any light is thrown upon the lesion by the character of the headache; this varies very much in both affections, and may be very trifling in either. The same may be said of changes in the optic disk; excepting that, whilst a normal optic nerve is not very rare in tumour, it is almost inconceivable in basal meningitis with marked exudation.

LECTURE II.—PROGNOSIS AND TREATMENT.

Gentlemen,—In my last lecture, the subject of cerebral syphilis was studied from a diagnostic point of view; to-day I shall direct your attention chiefly to the prognosis and treatment of the malady. To

be able to give a correct idea of the future of any individual case of disease, it is necessary to have a knowledge of the usual course of the affection. Cerebral syphilis is, for the most part, a chronic disorder, which, when left to itself, eventuates almost without exception in death, but which, when properly treated, usually yields rapidly to remedies. The prospect of success in any case depends, of course, very largely upon the stage at which it is first seen; but it is remarkable how much of serious organic destruction assisted nature will often restore. Head-aches the most violent and persistent will fade away, paralysis complete and extensive will disappear, mental failures and aberrations of most marked type will yield, and the wreck of a man be restored to the full glories of American citizenship. Still, there are patients in whom the greatest skill fails; and the important question is, can we distinguish the tractable from the intractable cases? Not always can this be done, but the general experience certainly warrants the clinical rule—always give a very guarded prognosis where the symptoms of cerebral syphilis are coincident with those of syphilitic cachexia. When cachexia does not exist, a bright future should be predicted, unless there be evidence of total destruction of important portions of the cerebral centres.

Experience has, however, taught me that a favourable prognosis should not be made with absolute-ness, on account of the danger of some of the symptoms or accidents of the disease, and on account of the occasional occurrence of grave and even fatal acute exacerbations. I remember a case of cerebral syphilis seen in consultation, in which one of the most notable symptoms was epilepsy. I stated unhesitatingly that the patient would get well, and was seemingly justified by the rapid progress of the case towards health, until one day this progress was unfortunately impeded by an epileptic spasm, in which, the suspension of respiration lasting a moment too long, asphyxia occurred. After death, we found small gummata in the pia mater at the base of the brain, and also in the velum interpositum, with inflammation and softening of the pons in the neighbourhood of one of the tumours. The influence which acute exacerbations exert upon the prognosis, and the still greater influence they have upon the treatment, justify their consideration here in some detail. Nervous syphilis is, as I have already stated, essentially a chronic disorder, and yet it may at any time take upon itself a most acute type. Some of you may remember a man suffering from partial aphasia, violent headaches, failure of memory, etc., who presented himself on a Monday last spring at our clinic. The history of syphilis was distinct, and the diagnosis, so far as cerebral syphilis was concerned, was plain. The same night, the unfortunate patient was seized at home with a violent convulsion. A neighbouring practitioner was called in, and, notwithstanding the past history, the present unconsciousness, the wild delirium, with screaming that echoed through the house and fighting that it took three men to control, diagnosed strychnia-poisoning, and told the friends that no doubt the doctors at the hospital had meant well, but that they had overestimated the patient's strength, and had given a dose of strychnia which was too large for him in his weak condition. The strychnia-poison treatment was earnestly kept up until the next Friday, when the medical man in charge, beginning to suspect that something was awry, despatched a

note to me, stating that he had a patient of mine suffering from symptoms of strychnia-poisoning. It was, of course, too late for treatment to be of any avail; and the necropsy showed, what was almost equally evident during life, that the cause of death was an acute meningitis grafted upon a chronic syphilitic inflammation of the cerebral membranes.

Not only may an acute attack supervene upon a chronic cerebral syphilis, but the disease may in its outset be of the most acute character. Perhaps, however, in this statement I am going a little too far. It may be that a gumma has in these cases been lying concealed. Whether this be or be not the case I have no evidence to decide; but certainly, so far as symptoms are concerned, the attack may be most sudden and acute. Some years since, I saw, in consultation with Dr. Fricke, a case of this character, which I shall narrate directly, as it portrays not only the occasional acute character of the disorder but also the proper method of treatment in such cases.

What, then, ought to be the treatment of an acute cerebral syphilis? Very much that of an acute, non-specific cerebral attack of similar type. If there be a violent epilepsy, with the epileptic status, nitrite of amyl, anæsthetics, antispasmodics, and other usual remedies should be employed. If the pulse, the fever, the *tout ensemble* of symptoms, indicate intense cerebral congestion, or cerebritis, free venesection should be used. In any case of doubt, you should remember that it is far safer to bleed in specific epilepsy than in a threatening similar attack of non-specific character, because in the latter case there is little hope of removing the cause, whilst in the syphilitic patient there is every reason to believe that, if time be gained, remedies will remove the disorder. Violent specific meningitis should receive the same treatment as the non-specific disorder: bleeding, local and general, blistering, and mercury. In the previously mentioned case of acute meningitis supervening upon the chronic disease, the man should have been bled at once, *ad deliquium*. If he had been set up in bed, a large orifice made, and the blood allowed to pour forth until syncope came on, very probably to-day he would have been alive and in health.

In Dr. Fricke's case, the man, who believed himself to be in perfect health, felt very wretched and heavy one afternoon whilst out attending to business, and, returning home, sat down in his shop. He soon became semi-unconscious, and was helped upstairs to bed, and directly afterwards was seized with severe convulsions and delirium. A homœopathic practitioner was sent for, and a couple of hours later, the convulsions becoming more and more violent, Dr. Fricke was summoned. He found the patient raving, and furiously convulsed with both tetanic and clonic spasms. At first he employed the classic remedies of a mild character, such as assafoetida clysters, counter-irritation, etc.; but the mustard-plasters were kicked across the room, and doctor and syringe-pipe followed them with remarkable promptness. All the remedies simply redoubled the violence and frequency of the paroxysms; their application was the signal for a furious outburst; the least touch produced frightful contortions and spasms. Then the lancet was used; and when a quart of blood had flowed, quiet had been restored, and even the cheek of the bleeder began to blanch, but Dr. Fricke, with finger upon the pulse, ordered him to continue. When half-a-pint more had been taken, the pulse

began to fail very markedly, and the arm was bandaged.

After an hour or so, twitchings of the muscles and other symptoms indicative of a recurrence of the convulsions coming on, about a pint more of blood was taken from the temples by cupping, and the patient became as quiet and relaxed as a sleeping infant. The next day he awoke, weak, but free from pain and out of present danger. The subsequent history of the case revealed the nature of the attack; and when once the specific character was suspected, and the appropriate remedies employed, a gradual restoration to health was effected.

The treatment of chronic cerebral syphilis is essentially a simple one. It has been considered to consist simply in the free administration of iodide of potassium, and in the majority of instances this is true. In giving the iodide, it should be remembered that syphilitic patients bear it in enormous doses; that in many cases it seems to be both food and drink to them, the nourisher of well-being and moral restoration; that often, like the bromide in epilepsy, it is necessary for the patient to take it persistently for months and even years—even long after the disappearance of all symptoms. After trials of various methods, it seems to me that its administration in simple water or in infusion of chamomile affords the best method of giving it. Compound syrup of sarsaparilla certainly covers its taste better than anything I have tried, but is apt to sicken the stomach. In regard to the dose, there is rarely any use in giving less than a drachm a day, and frequently a drachm and a half, and even two or three drachms, are well borne. My rule is to commence with fifteen grains four times a day, and rapidly increase the dose until symptoms of iodism are induced, or until a daily amount of at least two drachms is reached.

I wish here to call your attention to the use of mercury in the disorder. I am convinced that it has come to be too much the custom to rely upon the iodide. When there is no cachexia, and therefore no contra-indication to mercury, it acts more quickly, and even more effectually, than the iodide, and in many cases the only objection to its use is prejudice.

I have seen a syphilitic epilepsy, which had resisted the most heroic doses of the iodide, disappear like magic before a mild ptyalism. I usually employ the blue mass properly guarded with opium as one of the mildest, and at the same time most efficient, of the preparations; but it does not make much difference which form is selected; only remember this: Give the mercury boldly and persistently until ptyalism is induced, but give it cautiously; watch the mouth, and the moment the gums become the least sore, reduce the dose, but do not withdraw the remedy altogether: keep the mouth a little sore for some days or weeks, as may be necessary.

In regard to the use of counter-irritants, I have not employed them to any extent in chronic cerebral syphilis. They may be of value, especially in cases of meningitis, but they are very annoying, and in most cases you can get along without them.

THE GREAT THERMAL ESTABLISHMENT AT DAX (LANDES, FRANCE).

No. 49, tome ii., of *La Revue Médicale* (December 1, 1875), edited by Dr. Sales-Girons, is filled from beginning to end with eulogies and descriptions of

the baths and establishment for invalids, which were founded at Dax about 1871. Dax, which takes its name from Aquæ, by corruption Acqs, and lastly D'ax or Dax, is situate in the rich valley of the Adour, in the department of the Landes. It lies between the 1° and 2° of W. longitude from Greenwich, between 43° and 44° of latitude N. The province is of course Gascony. The ancient name was Aquæ Augustæ Tarbellicæ. The town, which is still partly surrounded by the old Roman ramparts, on the left bank of the river Adour, and its suburbs (called Sablar) on the opposite bank, contain together about 10,000 inhabitants. It boasts a castle, a high church which was once a cathedral, the remains of the bishop's palace, a communal college, etc. The chief attraction of the place is without question the thermal springs, which have a temperature varying from 86° to 166° Fahr. [The hot springs at Bath (Somerset) have a temperature of 112° to 116° Fahr.] 'The mildness of the climate, which is at once mild and dry, especially recommends it to those who have most reason to dread cold and damp, and in particular, to rheumatic invalids,' says Dr. Rotureau, in his book on 'Les Eaux Minérales de l'Europe.' The town of Dax is situated between Arcachon, Biarritz, and Pau, all well-known winter resorts. It is near enough to the sea to acquire an almost uniform temperature, whilst environed by and embosomed in some thirty kilomètres (nearly twenty miles) of pine forests. It is about four hours journey from Bordeaux, two hours from Pau, one hour from Biarritz, and twenty-two or twenty-three miles from the sea-coast. There are mud-holes (*boues*) of warm sulphuretted minerals, and the mineral waters at a temperature of 140° are chiefly of sulphate of calcium in solution. The thermal establishment, built over these in 1869 and opened two or three years later, occupies a surface of some 1,532 square yards. The ground-floor or basement is entirely occupied with the different bath-rooms, rooms for electrifying, for vaporising, etc.; and all open into a large glazed gallery, which occupies the interior of the edifice or square. On the first floor the best bedrooms, dining and reading rooms, etc., also open into a large glazed gallery. These two conservatories, or glazed galleries or glass saloons, are 306 yards in length, and in them the air is kept constantly at temperatures of from 60° or 65° to 77° or 82° Fahr. These galleries are also well ventilated. Besides the advantages of the climate, invalids have here a complete set of baths of various kinds, of silicated, ioduretted, sulphurated, and chloro-ioduretted ferruginous waters, which can be bathed in, drunk, or taken in a pulverised form. There is a comfortable home for the invalid, who can get air without leaving the building; there are electrical appliances and careful medical treatment, under the supervision of M. Larauza, the medical superintendent. This watering-place is especially adapted for: 1, patients suffering from rheumatic affections of all kinds; 2, those suffering from throat and chest diseases, or from delicacy of these organs; 3, those suffering from neuroses and paralysis; 4, all those suffering from congestive maladies, especially if due to cold; 5, lastly, sufferers from anæmia.

There is one gallery especially devoted to the mud-holes. In a long gallery there are numerous small cabinets or bath-rooms quite isolated from one another, each containing a kind of bath or basin forty by fifty-two inches, which is filled by the warm mud

or *boue*. Alongside of this is a warm bath to clean off the mud. A liberal table is kept here; there are amusements of various kinds, and it is consolatory to know that in the great floods of 1873 and 1875, in which the Adour rose eighteen feet above its ordinary highest level, this establishment, though on its banks, was perfectly protected by its own walls and breakwaters. Even in the depth of winter, swallows and summer-flies are often seen at Dax. If a little less warm than Nice, it is far more protected and less relaxing. The charges are by no means excessive, being about 75 to 100 francs (three to four guineas) a week for patients, including everything, and from 50 to 75 francs (two guineas) for their friends; whilst servants and children under ten years of age are only charged 37 or 38 francs (about 30s.) per week. When it is remembered that these charges include the medical advice and treatment, as well as board, they cannot be considered anything but very moderate. We understand this tariff is subject to some modifications by special agreement with the medical superintendent.

W. BATHURST WOODMAN.

ANATOMY AND PHYSIOLOGY.

WALDEYER ON CONNECTIVE-TISSUE CORPUSCLES.—W. Waldeyer (*Archiv für Mikroskopische Anatomie*, Band xi. p. 176, and *Centralblatt für die Medicinischen Wissenschaften*, no. 3, 1876) considers the following subjects.

1. *The so-called Flat-cells* ('Platten Zellen') of the *Fibrillar Connective Tissue*.—Under this title the author groups the cells of the loose fibrillar connective tissue and of the formed fibrillar connective tissue of tendons and fibrous membranes. The tendon-cells do not represent simple rectangular plates, but are complicated structures, which are best characterised as 'compound plates,' and may be compared to the form of a wheel. A clear conception of the form of these cells is best obtained in the following way. Open a book so that its leaves are kept asunder in groups of four, five, or six, which meet each other at various angles; the whole then makes the same impression as a tendon-cell in miniature. One has not to do with one plate, but with several which are disposed in different ways irregularly one over the other. The margins of these plates are not cut off straight, but project into numerous fine processes, often of considerable length, so that the processes from two neighbouring cells may anastomose; just like the tendon-cells are the so-called fixed cells of fibrous membranes and those of the loose connective tissue. In fact, these cells are neither simple nucleated plates nor spindles, but are 'compound plates,' of which one, the 'chief plate' (*Hauptplatte*, W.), generally contains the nucleus. The other plates are of smaller size, and appear like little wings, which are attached to the chief plate at acute or almost right angles, and which, just like the margins of the chief plate, send out many small thread-like processes. Where bundles of fibrillar connective tissue are present, they insinuate themselves into the spaces which exist between two plates or wings resting on each other. The cells never lie however, directly on the bundles themselves, but are always separated by a more or less strongly developed interfascicular, *i.e.* interlamellar cement from the proper fibrillar mass, so that the

cells themselves are buried in cavities in this cement ('Saftraüme,' 'Juice spaces' of von Recklinghausen). The 'elastic stripes' of Boll, according to the author, only represent the side view of a neighbouring plate.

2. *The Fixed Cornea-corporcles.*—In the *Handbuch der Augenheilkunde*, by von Graefe and Sämisch, the author has described the cornea-corporcles as flat bodies, possessing a considerable quantity of finely granular protoplasm arranged around a nucleus which towards the periphery however, passes into a more homogeneous plate, provided with obvious processes which partly anastomose with those of other cells, and partly end free, so that all the *Saftcanälchen* are not filled with processes of the cornea-corporcles. To this description the author adds that the cornea-corporcles also, like those of tendon and connective tissue, are provided with delicate secondary plates. The nuclei lie in the centre, near the place of junction of the plates; the latter themselves—mostly two or three secondary plates to one chief plate—become quite thin, and are like a veil at the margins, and are there provided with processes.

3. *Large Connective-Tissue Cells, rich in Protoplasm.*—Besides the cell-plates, there occurs in the connective tissue another group of cells, not so numerous, but quite as important as these; large, more rounded cells, rich in protoplasm (embryonal-cells of the connective tissue or plasma cells, Waldeyer). They are found sporadically in the subcutaneous connective tissue, and in all fibrous and serous membranes, mostly in the neighbourhood of the blood-vessels. They are distinguished from the wandering cells by their greater dimensions, and by the absence of amoeboid movements. Certain peculiar groups of cells, whose histological significance up to this time was not obvious, are nothing more than groups of these plasma-cells. The author ascribes to this category: 1. The cells of the so-called interstitial substance of the testicle; 2. The cells of the hypophysis cerebri; 3. The cells of the carotid gland; 4. Large round cells, which are found not unfrequently as an adventitious covering on the vessels of the brain; 5. The cells of the suprarenal capsules; 6. The cells of the corpus luteum; 7. The so-called decidua or serotina cells of the placenta. It is characteristic of these cells that they always appear arranged directly around the blood-vessels, which they cover as with sheaths. The author proposes the name of 'perivascular cellular tissue' for them.

ERLER ON THE RELATION OF THE EXCRETION OF CARBONIC ACID TO CHANGE IN THE BODILY TEMPERATURE.—H. Erler (*Dissertation*, Königsberg, 1875, and *Centralblatt für die Medicinischen Wissenschaften*, no. 13, 1876) employed in his experiments rabbits, a caoutchouc cap being firmly fixed over the nose. The respiration was kept up through Müller's valve, and the expired air passed through a Geissler's potash-apparatus. The increase in weight of this apparatus at the end of the experiment represented the amount of carbonic acid excreted. In front of this apparatus there was placed a vessel with a solution of caustic baryta, in order to absorb any carbonic acid which might not have been taken up by the potash. In some cases, where the difficulty of respiration appeared too great, the apparatus was connected with an aspirator.

1. Carbonic Acid given off when the Animal was

tied down.—In every animal the amount of carbonic acid given off in the free condition was estimated for several periods of ten minutes each; then the animal was tied down, and the amount again estimated several times at the same intervals. The following table gives the mean for the carbonic acid given off:

No. r.	Carbonic Acid in ten minutes.	
	Free.	Tied down.
1. .	0.050 grammes.	0.042 grammes.
2. .	0.074 "	0.059 "
3. .	0.045 "	0.029 "
4. .	0.050 "	0.031 "
5. .	0.045 "	0.022 "

The weight of the rabbits varied between 1,020 and 1,372 grammes. The variations in the values are pretty considerable, but in every case the carbonic acid given off diminishes when the animal is tied down, and simultaneously there is a fall in the temperature.

2. *Carbonic Acid given off in the Paralysed Condition.*—This was produced by dividing the spinal cord. The temperature did not rise after this operation, but fell without exception, and that continually, as has been observed several times before. In three experiments the mean values were the following:

No. r.	Carbonic Acid in ten minutes.	
	Normal.	Paralysed.
1. .	0.046 grammes.	0.008 grammes.
2. .	0.074 "	0.017 "
3. .	0.091 "	0.016 "

3. *Carbonic Acid given off during Artificial Cooling.*—For this purpose the animals were placed in a double walled zinc box filled with ice. The body-temperatures obtained by this means are indicated in the following tables:

No. r.	Lowest Temperature of body.	Cent.	(90°32 Fahr.)	Carbonic acid in ten min.	
				Normal.	Cooled.
				0.049 gr.	0.024 gr.
1. .	32°34'	90°32	Fahr.)	0.049 gr.	0.024 gr.
2. .	32°7'	90°86	"	0.039 "	0.014 "
3. .	33°6'	92°48	"	0.034 "	0.016 "
4. .	34°4'	93°92	"	0.061 "	0.028 "
5. .	33°2'	91°76	"	0.039 "	0.016 "

4. *Increased Body-Temperature.*—The box employed for these experiments, instead of being filled with ice, was filled with warm water. The quantity of carbonic acid given off increased when the temperature of the body began to rise, but sank again as soon as the animals became dyspnoic, which generally occurred at 39.4° C. (102.92° Fahr.). If the temperature of the surroundings be very high, then the dyspnoea occurs so soon that no increase of the carbonic acid is to be observed. As the animals for this experiment must be tied down, the carbonic acid at the beginning of the experiment diminishes somewhat compared with the normal.

5. *Carbonic Acid given off by diminution of the Bodily Temperature, the Skin being covered with Varnish.*—Here also the excretion of carbonic acid fell, and simultaneously the temperature. The mean value of carbonic acid excreted in all the experiments was in the normal state 0.033, in the varnished 0.013 grammes. The temperature was reduced to 32.3° C. (90.14° Fahr.). Thus the amount of carbonic acid excreted and the temperature of the body stand in direct dependence one on the other.

MEYER ON RED AND PALE TRANSVERSELY STRIPED MUSCLES.—E. Meyer (*Reichert and Du Bois-Reymond's Archiv*, 1875, p. 217) found that the primitive bundles of the red semitendinosus were

distinctly thicker than the fibres of the pale adductor. While ten fibres of the semitendinosus, from a longitudinal section, lay in the field of the microscope, it required sixteen to twenty of those of the adductor to fill the same space. The nuclei of the fibres of the red semitendinosus were much more numerous and broader than those of the adductor. In the former five nuclei appeared on transverse sections, in the adductor only two. The capillaries of the semitendinosus were also characterised by having little aneurismal dilatations. It is shown that all the red muscles of the rabbit have not the same structure as the semitendinosus. Thus it is proved that the cause of the difference of the semitendinosus and adductor is different from that which occasions the difference between the red and pale muscles of the rabbit. There must be a special relation between the semitendinosus and the adductor which does not exist between the latter and the other red muscles. This relation can only consist in factors, which are present not only in the rabbit, but belong to the whole tribe of the rodents. The difference between the semitendinosus and adductor is not a special peculiarity of all rodents; it is only found in the guinea-pig. In as far as the rabbit and guinea-pig, in opposition to the other rodents, have this in common, viz., that they have been domesticated, the author believes that the cause of the partial change of colour in the muscle is to be ascribed to the imperfect movement of the parts in consequence of the domestication. From this point of view, it must be shown that other animals which have undergone a similar process of breeding show differences in colour. In fact, similar conditions (as far as the difference between the red and pale muscles is concerned) exist in the common fowl. Electrical stimulation showed that the semitendinosus of the rabbit passes into tetanus, when pronounced twitching is still clearly visible in the adductor. The semitendinosus seems to be used in a way differing from that of the other muscles of the rabbit; and the author believes that this muscle, in consequence of its being in constant use and in a state of tension in the living rabbit, has lost the power of passing rapidly from one condition into another.

SOCOLOFF ON THE SECRETION OF THE LIVER.—N. Socoloff (*Pflüger's Archiv*, vol. xi. p. 166) has tested the assertion of Huppert and Schiff, that glycocholic acid injected directly into the blood or absorbed from the intestine is for the most part again excreted by the liver. The author's experiments were made on a large dog with a biliary fistula. Solutions of glycocholate of soda were injected into the jugular vein (0.4 gramme and 0.8 gramme) and into the stomach (1 to 2 grammes). Before and after the injection the quantity of glycocholate acid in the bile, collected at intervals of half-an-hour, was estimated. Although in individual cases the quantity of bile increased, an increase of the bile-acids was not observed, and no glycocholic acid was detected in the bile excreted. The author therefore rejects the view of Huppert and Schiff. The increase of the secretion cannot be ascribed to the introduction of the water, but is rather to be regarded as the result of a specific stimulating action of the salts of the bile-acids.

RAJEWSKY ON ABSORPTION FROM THE HUMAN DIAPHRAGM UNDER DIFFERENT CONDITIONS.—A. Rajewsky (*Virchow's Archiv*, vol. lxiv. p. 186)

removed carefully the human diaphragm and stretched it, avoiding tension, over a funnel, or laid it on a plate and covered its abdominal surface with a thin layer of a solution of china ink in salt solution or with milk. The following results were obtained. 1. The human diaphragm has the property of sucking up fluids which contain suspended particles, just as is the case with the diaphragm of the rabbit, as was shown by von Recklinghausen. 2. The human diaphragm, when it has been changed by inflammatory processes, acquires the property of permitting fluids brought into contact with it to pass into its channels. 3. In diaphragms which have undergone inflammation by the smallest pressure there may be obtained an injection of the 'saftcanälchen system.' This system is connected with the lymphatic capillaries, and does not consist of mere spaces or slits, but of special canals, which are formed in the loose connective tissue. 4. Removal of the epithelial lining of the serous membrane, either naturally (by inflammation) or artificially opens new channels for the passage of the fluids, viz. the 'saftcanälchen,' which begin on the free surface of the serosa. 5. From the serous membrane, only small lymphatic stems can be followed into the subserous adipose tissue, where they become united into a network of the finest lymphatic capillaries, in each of whose meshes is placed a fat-cell. The experiments were made in the laboratory of Professor von Recklinghausen, of Strasburg.

VON PLATEN AND PFLÜGER ON THE INFLUENCE OF THE EYE ON THE METAMORPHOSIS OF TISSUE.—O. von Platen and E. Pflüger (*Pflüger's Archiv*, Band xi. p. 272, and *Centralblatt für die Medicinischen Wissenschaften*, no. 8, 1876) are of opinion that that condition of the brain which we term 'waking' is partly at least kept up by a summation of sensory stimuli; that the further waking condition of the brain causes a continual stimulation of almost all the centrifugal nerves, i.e. an increase in metamorphosis of tissue. A series of facts may be cited in support of this view—the rapid increase of the temperature of hibernating animals when they have been awakened by strong stimuli; the diminution in the production of carbonic acid during sleep, and also by the action of curara; lastly, the storing up of energy during sleep which cannot be attained so rapidly by simple rest. From this point of view, it appears probable that by removing all stimuli from the retina it ought to be possible to obtain a considerable diminution in the production of carbonic acid. The experiments of Moleschott on this subject, as the authors show, are not sufficient proof, because the greatest insensibility of the retina was not produced; and the same is true of an experiment by Pott.

The experiments of von Platen were made with Röhrig-Zuntz's respiration-apparatus on rabbits, in which tracheotomy had been performed. The rabbits respired pure oxygen, the amount consumed being read off directly. The carbonic acid was absorbed by caustic potash, and after acidulation with sulphuric or phosphoric acid was pumped out and measured. To exclude the light from the retina, rings of wood, in which was placed a piece of glass, were fixed in front of the eye. By means of a lid the light could be excluded. Each period, 'clear or dark,' lasted about twenty or thirty minutes. The periods alternated several times, and commenced sometimes with the one, sometimes with the other. Apart from a few

variations, the oxygen absorbed and the carbonic acid given off were greater in the light than in the dark. Of eight animals, in one minute the mean was :—

	In Darkness. Cubic Centimetres.	In Light. Cubic Centimetres.
Oxygen taken in . . .	120.465	140.665 = 100 : 116
Carbonic acid given off .	85.635	97.96 = 100 : 114

W. STIRLING, D.Sc., M.D.

GUDDEN ON THE REMOVAL OF THE KIDNEY AND TESTICLE FROM NEW-BORN GUINEA-PIGS.—The author (*Virchow's Archiv*, vol. lxvi. p. 55), found the following conditions in a full grown guinea-pig from which the left kidney had been removed immediately after birth. The left ureter was thinner than the right, and thinner than the ureters of another healthy adult animal examined for comparison. The duct was patent and its natural structures—epithelium, muscular, and fibrous layers—were present though somewhat less developed than normal. On applying a strong induced current, contraction was excited at the point of application without spreading to the neighbouring fibres, as was the case with the healthy ureter. Lastly, the left ureter presented a number of small diverticula involving all its coats. The right kidney was enlarged, its length being one-third as much again as the mean length of the two kidneys in the healthy animal; while its estimated bulk and actual weight were greater than those of the two normal organs together. The enlargement was clearly due, not to an increase in number, but to an increase in size of the various constituents; this at least was demonstrated in the case of the glomeruli and vessels, though not in the case of the tubules, on account of their varying diameters. It was not found that the heart was hypertrophied as a result of the operation.

Professor Gudden also removed both testicles under similar conditions, and found that the vasa deferentia and vesiculæ seminales were small, and that in proportion to the dependence of their development upon the presence and activity of the testicles. When one organ only was taken away, the vas deferens of the same side was thinner, and the corresponding half of the seminal vesicle was somewhat smaller.

ARNOLD ON THE CEMENT-SUBSTANCE OF SO-CALLED ENDOTHELIUM.—In the January number of *Virchow's Archiv*, p. 77, is an important paper by Dr. J. Arnold, who has made further researches into the nature of the substance uniting the so-called endothelium-cells (epithelioid cells.) For this purpose he has employed a new apparatus by which extremely small quantities of colouring matter were injected for long periods into the living animal. The materials used were a solution of sulphindigotate of soda, ferrocyanide of potassium, the part afterwards being washed with chloride of iron, so as to precipitate Prussian blue, and thirdly, Indian ink. Frogs and guinea-pigs were the animals experimented on; and the blood-vessels, lymph-sacs, peritoneal cavity, anterior chamber of the eye, and subcutaneous cellular tissue, were the parts into which the fluids were injected. In the case of the vessels, he obtained not only a network of coloured lines corresponding to the junction of their epithelioid cells, but also similar junction-lines in the perivascular sheath, as well as injection of this sheath, and the lymph-canalicular system of the neighbouring connective tissue, whence some of the fluids used passed into the serous cavities. On injection of greater

quantities, colouring matter was deposited even between the epithelial cells of the skin, glands, intestines, and in the lymph-canalicular system of the subcutaneous and intermuscular connective tissues. Other experiments sufficed to show that this deposit was the result neither of any action on the part of the cells, nor of mere imbibition, and that the lines of colour varied in breadth and distinctness with alterations in the tension of the vessel during injection. He therefore concludes that the epithelioid cells are but loosely connected, and the narrow space between them is filled with a fluid or almost viscid substance, which permits the passage of dissolved and suspended pigments, but that the appearance of the intercellular spaces varies according to the different conditions of tension of the endothelial membrane. The fact that solutions of metallic salts and dissolved and suspended colouring matters pass between the cells and reach the lymph-canalicular system indicates that the intercellular substance not only serves the purpose of a cement, but has important functional relations, holding an intermediate position between the vessel wall and the tissue on the one hand, between the vessel contents and the contents of the lymph-canalicular system on the other. The appearance of so-called stigmata he regards as due to the occasional increase in breadth of the fluid or viscid cement-substance.

F. TAYLOR, M.D.

BROWN ON THE ACTION OF BILE-SALTS ON THE ANIMAL ECONOMY.—Mr. J. Graham Brown (*Proceedings of the Royal Society of Edinburgh*, May, 1875) has carefully noticed the phenomena which follow the injection of the glycocholate and taurocholate of soda under the skin of rabbits. The quantity employed varied from ten to forty grains. The chief results are that a large dose of the bile acids kills the animal in from thirty hours to three or four days; the total nitrogen in the urine, as estimated by the hypobromite process, is increased; severe diarrhoea and drowsiness and somnolence increasing towards the end of life are often noticed. Albumen and hæmoglobin do not seem to have been present in the urine, as they always are after injection of the bile-acids into the veins. Only in one case was a trace of albumen present, and once or twice blood-corpuscles. Bile-acids are said to have been always present, but only rarely a trace of bile-pigment. The tests and the manner of using them, however, are not stated. A parenchymatous degeneration of the liver and kidney was also noticed, a fact not only made out by Feltz and Ritter, but so long ago as 1866 by Leyden. The hypodermic injections of bile-acids cause a destruction of the red corpuscles and apparent increase of number in the white, again resembling the results of injections into the veins.

[This research would doubtless have been greatly improved if the writer had made himself master of the views of Traube, Johannes Ranke, Röhrig, Schiff, and others, on the physiological action of the bile-acids. A contribution might also have been made to the discussion now going on between Hoppe-Seyler, Tarchanoff, and Naunyn as to the causes of the presence of bile-pigment in the urine, a subject which Mr. Brown touches, but does not fully enter upon.—*Rep.*]

J. WICKHAM LEGG, M.D.

HERZOG ON THE STRUCTURE OF TENDON.—Dr. W. Herzog (*Zeitschrift für Anat. und Entwicke-*

lungsgeschichte, Band 1, Heft. 3 and 4) examined transverse sections of the frozen tendo Achillis of the calf. The well-known stellate spaces and their connecting lines (so-called connective tissue corpuscles) appeared dark. The tendon-substance enclosed within these spaces and lines, designated by the author a primary bundle, was divided into a number of fields, separated from each other by clear anastomosing lines. In these fields the fibrillæ were seen as dark points. The author succeeded in filling the stellate spaces and their connecting lines with an injection mass, the result being a complete blue network.

[The drawing of these peculiar 'fields' reminds one at once of Cohnheim's fields in sections of frozen muscle. The reporter believes them to represent transverse sections of the structures he has lately described in tendon as primary bundles (seen lengthways), not to be confounded with the primary bundles of Herzog, which he termed secondary bundles.—*Rep.*]

G. THIN, M.D.

URBANTSCHITSCH ON THE ANATOMY OF THE OSSICLES OF THE EAR.—In the April number of the *Archiv für Ohrenheilkunde*, Dr. Victor Urbantschitch gives the results of the examination of the ossicles of fifty human ears. Some of these results are as follows.

Hammer.—The length of the hammer was on an average 8·5 millimètres. The short process averaged 1·6 millimètres in length. The long process was in an individual thirty years of age 2·5 millimètres, and in one of twenty years, 5·8 millimètres long. The manubrium, measured from the point of the short process to the lower end, ranged from 4·2 to 5·6 millimètres. The distance of the lower end of the manubrium from the periphery of the *membrana tympani* averaged in thirty-eight cases, 3·5 millimètres, from the inferior edge, 3·4 millimètres from the anterior border, and 4·6 millimètres from the posterior border.

Anvil.—The general distance of the upper end of the ambrosius-surface from the free end of the process brevis was 5·3 millimètres, and that of the lower edge of the same joint from the inco-stapedial joint 4·6 millimètres.

Stirrup.—The length averaged 3·7 millimètres; the breadth, measured from the middle of both limbs 2·3 millimètres, the distance of the upper arch of both limbs to the base of the anterior limb 2·2 millimètres, to that of the posterior limb the same. The breadth of the anterior limb averaged 0·6 millimètres, of the posterior 0·8 millimètres. The length of the base was 3 millimètres, the breadth 1·5 millimètres.

The *tensor tympani* is inserted into the manubrium generally to the extent of from 7 to 10 millimètre in breadth. The manner of its insertion was found to be very different. In nineteen cases it was inserted on the anterior surface, in twenty cases on the inner edge and anterior surface, in seven cases on the inner edge alone, in two cases on the inner edge and posterior surface, in two cases on the posterior surface alone, and in ten cases the tendon passed round the inner border, and was fastened on both the anterior and posterior surfaces.

The *stapedius* had an average length of tendon, measured from the summit of the pyramid to its insertion into the stapes of 1·2 millimètres.

MEDICINE.

SELIGSOHN ON A CASE OF HYDATID OF THE LIVER.—Dr. Max Seligsohn, a general practitioner in Berlin, remarks (*Berliner Klinische Wochenschrift*, February 28), that the interesting features of the following case, justify its publication with some detail. The following is a summary:—General jaundice, persistent pains in the lower part of the right half of the thorax, fatal termination with symptoms of asphyxia after fourteen days: *Post mortem* examination: Hydatid cyst of the liver, the sac of which was partly formed by the diaphragm. The existence of tæniæ was demonstrated two months before the jaundice occurred.

Mrs. C., aged thirty-nine, was known to Dr. Seligsohn since the year 1868, as an apparently healthy woman, who was in comfortable circumstances, and lived a very regular life. On February 7, 1874, she took a dose of koussou, for tape-worms, the result of which was so successful, that the tape-worm passed by her was not minutely examined. On April 10 she complained of gastric troubles, which increased so much by April 20, that she was unable to walk even a short distance, and was therefore seen at home, and found to be deeply jaundiced, as regarded both skin and mucous membrane. The patient, who had been very strong, though stout, complained of great general fatigue, and of great tenderness to the touch in the hepatic region. The tongue was pretty clean, but she had complete loss of appetite, and felt disgust at food. There was no fever. The exact limits of liver-dulness could not be determined, for the abdomen was much distended. On April 23, increasing weakness confined her entirely to bed. The pains in the hepatic region had increased, and extended to the lower half of the thorax on the right side. On percussion, there was dulness posteriorly on the right side as high as the inferior angle of the scapula; this extended also towards the left side as far as the extremely curved (cyphotic) spinal column; but towards the axilla the upper edge of the dulness was about two fingers' breadth lower. The left side of the chest exhibited exaggerated vesicular respiration. On the right side, the dull regions on auscultation only revealed very feeble breathing, and diminished fremitus. Only at the upper border of the dulness there were bronchial breathing and bronchophony. Over all the rest of the right chest there was feeble vesicular breathing. The heart-sounds were weak, but clear. Pulse 80, scarcely to be felt. Respirations 48 per minute. There was no expectoration. The jaundice was as before. The urine was slightly albuminous, and contained bile-pigment. Inspiration did not seem to depress the upper limits of the dulness. Next day, without any access of fever, the dyspnoea had greatly increased. Dry cupping on the right side gave no relief. She now lay on that side, and any attempt to move her brought on attacks of dyspnoea of great severity. It was at first thought that there was pleuritic effusion. Against this, there were the facts that breath-sounds were still

heard, and that the line of dulness was lowered in the axillary line. The increasing collapse, in so strong a person, and the great dyspnoea, contrasted strangely with the absence of febrile symptoms, and of any copious discharges. Drs. P. Guttmann and W. Koch, who saw her in consultation, imagined there must be pyæmic or septic processes going on—yet could not justify their opinion by the facts. They agreed as to the physical signs. The treatment was therefore directed to the symptoms, and consisted chiefly of senega with ammonia, and wine, etc. A few hours before death, a capillary puncture in the posterior and lower half of the right thorax gave exit to much thin, offensive, shreddy pus, without relieving the dyspnoea. She died in the forenoon of April 30.

The *post mortem* examination was limited to the thorax. On removing the sternum, a good deal of purulent serum escaped, and revealed a large tumour, surrounded with a thick envelope or sac. This filled almost the whole of the right pleural cavity, and nearly all the mediastinum, pushing the contents of the latter towards the left. It had a rounded summit, as high as the second rib, and extended downwards and forwards to the lower margin of the ribs. The right lung was compressed and flattened between the tumour and the chest-wall. The middle lobe of the lung was most flattened; the upper and lower lobes still contained air, were almost bloodless, but had some catarrhal secretion in the bronchi, etc. The covering of the tumour was formed by the right muscular and membranous portions of the diaphragm. An incision gave exit to a vast quantity of thin, bad smelling yellowish pus, intermixed with some hundreds of echinococcus-cysts of all sizes. The largest of these had a diameter of about three inches; the smallest hydatid was about the size of a pea. After about four-and-a-half litres of fluid (= one gallon nearly) had escaped, a large sac or cyst could be easily detached, the base of which was formed by the upper surface of the liver. The liver-structure was very slightly involved, whilst the diaphragm and pleura costalis and pulmonalis were intimately adherent to it. The inner surface of the cyst was rough and granular from fibrinous accretions. The liver was increased in size in all its diameters, and fatty. The heart, small and atrophied, had partly undergone fatty degeneration, and was pushed over to the left.

Dr. Seligsohn remarks that the criteria as to the upper limits of liver-dulness as distinguishing between pleuritic exudation and hydatids of the liver, on which Frerichs insists (*Klinik der Leberkrankheiten*, 1861, Theil ii. s. 242, vol. ii. of Dr. Murchison's translation, 'New Syd. Society p. 247,') failed in this case; indeed the border in the axillary line was concave rather than convex. The adhesions of the diaphragm, the corpulence of the patient, and the absence of bulging in the intercostal spaces, all increased the difficulties of diagnosis. If Frerichs speaks somewhat confidently as to the ease with which such tumours can be diagnosed, it is consolatory to find Davaine (*Traité des Entozoaires et des Maladies vermineuses de l'Homme et des Animaux Domestiques*, Paris, 1860, p. 437), quoting a series of such cases to prove that hydatids of the liver are often not diagnosed correctly, and are often confounded with pleurisy and hydrothorax. Thus Gooch had a case in a girl, aged nine, reaching as high as the clavicle, and containing some five pints of fluid. Puncture a little before death brought away only a little fluid. Dolbeau (*Étude sur les Grandes Kystes de la Surface convexe du Foie*, Paris, 1856),

had a case in a man, aged fifty-eight, who had suffered from pleurisy in the right side, with great dyspnoea. Here, too, the cyst was covered with the diaphragm, reached the second rib, compressed the whole right lung, and extended five fingers' breadth into the left thorax. Mercier and Combes had two similar cases, also mistaken for hydrothorax and pleuritic effusion. Davaine quotes another case from Duplay and Morel Lavallé, of a solitary large hydatid cyst, taken for pleuritic effusion. On the other hand, Frerichs gives a case in which the diagnosis was verified by a puncture in a woman aged thirty-eight. But here there was pointing, and the diagnosis was assisted by the discovery of leucin and succinic acid in a clear fluid, free from albumen. The cyst here was 9½ inches in diameter, and contained thirteen pounds of bright amber-coloured slightly turbid fluid, and there were echinococci on the inner wall of the cyst. (See Frerichs, *loc. cit.* English edition, vol. i. page 55; vol. ii. page 233.)

Dr. Seligsohn further remarks that the case is peculiar in several of its symptoms. There is first the jaundice which ushered in the fatal termination. It is rare in hydatid tumours of the liver to meet with any disturbance of the biliary functions, or of the portal circulation. Both jaundice and ascites, and severe dyspepsia are all rare. Davaine (*loc. cit.* p. 457), says that for the production of jaundice we must have (1), a somewhat extensive parenchymatous hepatitis, or (2), the echinococci must be discharged into either the biliary passages, or into the gall-bladder, through a communication with these being formed, or (3), the tumour must implicate either the common bile-duct, or some large hepatic bile-duct. As the *post mortem* examination showed no hepatitis and no pressure of the tumour on the bile-ducts, we are forced to conclude that the cyst communicated in some way with the biliary passages. According to Frerichs (*loc. cit.* Th. ii. s. 239; Dr. Murchison's trans. vol. ii. p. 119 and 230), such communications are seldom diagnosed in life. We may indeed suspect them, when jaundice occurs suddenly in such cases, or there are symptoms resembling gall-stone. Imperfect as was the *post mortem* examination in this case, yet the colour of the fluid and of the hydatids showed that bile had overflowed into the cyst. These communications are formed by the progressive growth of the cysts, just as they invade and destroy bronchi, blood-vessels, and the intestine. Rokitsansky, Budd, and Cruveilhier state that this influx of bile stops the growth of, and, indeed, kills the echinococci. It must remain doubtful, in this case, whether branches of the liver veins were not also laid open at the same time, and pyæmia and phlebitis thus set up, as mentioned by Charcley (Davaine, *Obs.* xciii.) and Bowman. The rapid course of the disease did indeed resemble pyæmia, or septic poisoning. The pressure of so large a tumour could scarcely help contributing to the fatal end. The local pains, according to Frerichs, are due to inflammation around the cyst.

Another point of interest is the presence of tape-worms two months before the jaundice sets in. This seems to be a solitary observation, and was, perhaps, only a coincidence. Küchenmeister thought that echinococci escaping into the alimentary canal might develop tæniæ in the same host (see 'Küchenmeister über Cestoden in Allgemeinen,' Zittau, 1853, s. 54). For this reason he blames Bilharz, who found the Tænia nana in great quantities in the duodenum of a child dying of meningitis, for not searching for

cicatrices in the liver or other parts, or other remains of hydatids (Leuckart considers the *Tænia nana* totally distinct from the *Tænia echinococcus*). But according to Pallas, Götze, and Bremser (R. Leuckart's 'Die Menschlichen Parasiten,' 1863, s. 333), no *tæniæ* have ever been raised from the human *echinococcus*. Küchenmeister, Zenker, and Levison in vain attempted to rear them "by feeding dogs and cats with human *echinococci*. On the other hand, Von Siebold ('Ueber Verwandlung der *Echinococcus*-brut in *Tænia*,' *Zeitschrift für Wissenschaft. Zoolog.* 1853, Bd. iv. s. 410) is convinced from experiments by feeding with *Echinococcus veterinorum*, that *echinococci*-germs brought whilst fresh and living into the digestive organs of a dog, develop under peculiar circumstances into a sexual mature tapeworm possessing only a pair of 'joints' (*Tænia echinococcus*). Röhl, however, (*Verh. d. physikal. Med. Ges. zu Würzburg*, 1852, s. 55) who reports two such cases in which he found similar triple-membered young individuals in the intestinal canal of dogs along with grown-up tapeworms and cucurbits, considers these small creatures to be the first stage of development of *Tænia serrata*.† Meanwhile, in thirty-six cases narrated by Davaine (*loc. cit.*), in which human hydatid cysts emptied themselves into the bowels, no trace of tapeworm was found. To these we may add, thirty-two cases of Davaine's, in which hydatids were got rid of through the bronchial tubes. For as these had to pass through the mouth, often for many months, it is clear that there were great risks of their being swallowed. In twelve of these cases there were *post mortem* examinations, but no *Tænia echinococcus* was ever discovered. If to these we add Frerich's case (*loc. cit.* Th. ii. s. 257; Dr. Murchison's trans. vol. ii. p. 261) in which four bile-tinged *echinococcus*-cysts without any hooklets either free or attached, were passed in the stools, but no tapeworms were discovered, we can scarcely consider the presence of tapeworms in the present case as more than accidental. As Charcot (quoted by Frerichs) observed a case in which the common bile-duct was completely blocked by hydatids, it is, however, very probable that the jaundice in the pres-

ent case was caused in a similar way, and that there was a communication with the biliary passages.

W. BATHURST WOODMAN.

SCHÜLEIN ON THE DISTRIBUTION OF HEAT IN THE COURSE OF FEBRILE DISEASES.—The discussion on this subject is continued by Dr. W. Schüle in Virchow's *Archiv* for January, 1876. His observations on the peripheral temperature were made by fixing the bulb of a thermometer between the first and second toes, in such a manner that they should completely cover it. The temperature of the skin thus obtained was compared with that reached by a thermometer placed in the axilla. The results were the following. 1. In healthy individuals the temperature of the skin is subject to frequent variations. 2. In the course of typhoid fever, peritonitis, acute rheumatism, erysipelas, puerperal endometritis, miliary tuberculosis, and caseous pneumonia, there are constant oscillations, which are independent of the temperature in the axilla. 3. On the other hand, in measles, scarlatina, and croupous pneumonia, the temperature of the skin rises pretty uniformly with that of the axilla, and in the two latter diseases remains constant or follows the slighter axillary variations. 4. In rigor a depression of the surface temperature accompanies the rise in the axilla. The observations agree in the main with those of Jacobson, already noticed in this journal (p. 107), with this exception, that they are in favour of the occurrence of paresis of the arterial muscular tissue in pneumonia, measles, and scarlatina.

DEUTSCH ON DROPSY AFTER AGUE.—In the *Medicinisch-Chirurgisches Centralblatt*, for March 10, 1876, Dr. Deutsch records the case of a boy, aged four years, who was brought to him in the winter with ague, at first quotidian, later of irregular type. The spleen was moderately enlarged. In the spring he had œdema of the eyelids and ankles, which subsided, but again appeared and disappeared. In the summer the boy had general anasarca, and was so bloated that he was unable to sit up or even to move. After various domestic remedies had been tried without avail, the dropsy spontaneously yielded, and enormous quantities of urine were passed. In a few weeks the boy was well; there was no fluid, no fever, and no enlargement of the spleen, but the skin hung loosely about his limbs, and the abdominal parietes were marked with atrophic lines. [The interest of this case is much diminished by the absence of any note as to the character of the urine, further than that it was abundant during the subsidence of the anasarca. The author, however, publishes it as a case of remarkable recovery without treatment.—*Rep.*]

F. TAYLOR, M.D.

MACSWINEY ON CIRRHOSIS OF THE LIVER.—In concluding the report, with comments, of a case of cirrhosis of the liver, in the *Dublin Journal of Medical Science*, for February, Dr. MacSwiney says: There are, I venture to say, few diseases to be met with which present such a number of unsolved or disputed questions on points of importance as cirrhosis of the liver. At present, the following inquiries, relating to various features of the disease, still remain to be answered.

1. Whether it is an inflammatory exudation or a degenerative process which precedes the atrophy of the liver in cirrhosis?

2. Is true cirrhosis ever due to any other cause but

* Compare with this the experiment of B. Naunyn (*Reichert's und Du Bois Reymond's Archiv*, 1863, s. 412-416). He fed a dog with the scolices from a human *echinococcus*, and six weeks after, when the dog was killed, the upper part of the intestines beginning at the pylorus) were filled with a sort of tape-worm most resembling the *T. echinococcus* of Von Siebold.

† It appears from a reference to a communication of Cauvet's (*Virchow-Hirsch. Ber.*, f. 1874, Bd. i. ii. Abth. s. 363) that both he and Pruner-Bey have met with *Tænia medio-canellata* in Syria as well as *T. solium*. The former seems even in Berlin to be the commoner variety (Robinski and Fritsch in the *Berlin. Klin. Wochenschrift*, no. 37, for 1874). According to Cauvet, the same man in whom the *T. medio-canellata* is found, has been the host for the worm in its earlier stages. This opinion (not the common one) is founded upon a single case, in which Cauvet found a hydatid in the diaphragm of a child, and in the inner wall of this cyst there was an embryo, with four large suckers, but no circle of hooks. In the original (Cauvet, *Gazette Médicale de Paris*, 1874, no. 33, p. 412) he states also, 'en examinant un lambeau du diaphragme d'un boeuf d'ailleurs en très bon état apparent, j'aperçus sous la plèvre une sorte de petite élévation paraissant remplie de sérosité.' After careful preparation, he finally isolated a bladder of the size of a hemp-seed, on opening which he found bodies attached to the inner wall, which when examined by a lens, exhibited four suckers and no hooklets. 'Je crois,' concludes Cauvet, 'avoir trouvé le cysticerque de *tænia inermis*.' It does not appear that Arnould (*Gazette Médicale de Paris*, no. 34, p. 425) is really opposed to this view of Cauvet's.

drinking undiluted spirit? And if it be sometimes due to other causes, which is the generally received doctrine, then—

3. What are the other causes of true adhesive hepatitis?

4. Is the disease caused by spirit-drinking different from the other forms, not only in cause, but also in its anatomical characters?

5. Are the different so-called varieties of cirrhosis, which are often undistinguishable by their symptoms during life, anatomically distinct?

6. On what does the swelling of the spleen in this disease depend?

7. Can the disease be cured in the early stage?

8. What is the nature of those cases where the symptoms are absent during life, and the disease is for the first time recognised at a necropsy?

DISEASES OF CHILDREN.

SEELIGMÜLLER ON SCLEROSIS OF THE LATERAL COLUMNS OF THE CORD IN FOUR CHILDREN OF THE SAME FAMILY.—The cases came under the observation of the author in January 1876 (*Deutsche Medicinische Wochenschrift*, April 22 and 29, 1876). The family history, which was carefully inquired into,

was remarkably good, with one significant exception—that the parents were first cousins. There was no evidence of syphilis. Seven children—six girls and one boy—were the result of the marriage. Of these, the eldest, aged eleven, was quite healthy; the second, aged ten, was in an advanced stage of the disease; the third was, if anything, worse still, but was not seen; the fourth, a boy, aged six years and nine months, was in the middle stage; the fifth and sixth were healthy; and the seventh, aged one year and nine months, was in the first stage of the affection. The disease began in a similar way in all. Strong and healthy when born, they continued so up to the age of about nine months, when a change took place. Able previously to sit up without trouble, they began to lose this power, and would fall to one or other side; later, the head and chest sank forward. At the age of two years, attempts were made to teach them to walk, but their efforts resembled those of an infant six months old. This was exemplified in the youngest patient, who, when supported under the armpits, made jumping movements, the legs being raised from the ground simultaneously. Subsequently, the children learnt to support themselves with difficulty against a chair, but even this power was lost again. The boy had lately been rapidly losing ground in this respect; he could still, however, drag himself about in bed, and, by means of a specially constructed chair on wheels, could walk. The two eldest children, when supported in the upright position, could not put one foot before the other; even when lying down, they were unable to move, the upper extremities being useless as supports. The youngest girl could sit for a short time on the table, but cried all the time, and soon fell to one side; she sat with her head and chest inclined forwards, the spine equally curved, and the thighs greatly abducted; when on the lap, however, she could move her arms and legs in all directions.

Contractions at the joints were present in a high degree in the three eldest. In the eldest girl, the hands were adducted and pronated; pain was produced by attempts at passive supination, and the hand, when released, jerked back to its old position. The fingers were rolled in towards the palm, but she could still extend them, though very gradually and with great difficulty. The grasp was still perceptible; the right better than the left. The elbows were slightly bent, and nearly fixed. The knees were half flexed, but could, with great force, be moderately extended or flexed still more, though on leaving them, they sprang back with a jerk. The feet were in the position of advanced equinovarus; the tendines Achillis were perfectly rigid. All attempts at passive movement produced considerable pain. The boy was put under the complete influence of chloroform, and the rigidity of the joints then so increased that the whole body could be raised from one leg and held out like a piece of wood. The youngest girl had so far no contractions.

Atrophy of the muscles was marked in the two eldest under observation. With the exception of those of the face, it was evenly spread over the whole system. The wasting in the case of the girl was considerable, so that the head seemed too large for the attenuated neck, and was moreover unsteady. The parents were confident that in all three the wasting was not visible for some time after the loss of power showed itself.

In the eldest child, the reaction of the tibial and

peroneal nerves was normal with both currents; but the irritability of the muscles was decidedly lowered everywhere. Of those on the back of the forearm, the supinator longus alone responded promptly. In the youngest girl, faradaic excitability of both nerves and muscles was perceptibly lowered in all extremities, but especially in the left lower. Galvanic excitability was lowered in the same way, and in the tibial nerves was almost *nil*. Ordinary reflex irritability not increased. That of the tendons, however, was present in a high degree in all. Fibrillary contractions were markedly present in the eldest girl, and could be produced by simply blowing on the skin. Sensibility was normal in all.

Of the symptoms noticed by the parents, that which made its appearance last was the gradual loss of the power of speech. Thus, in the two eldest girls, this was tolerable until their sixth year, when it became less and less distinct; until finally, only inarticulate nasal noises could be made. In the girl, the lips, soft palate, and uvula, were all paralysed, and the tongue lay in the mouth like a mass of dead flesh: its tip could be advanced only as far as the teeth. In the boy the same symptoms were present, but in a somewhat less degree. The youngest child could say a few words, but they had a slightly nasal tone. Swallowing in the two eldest girls was difficult; in the boy, tolerable. The form of the skull was unusual in all, but especially so in the eldest. It was very broad between the parietal eminences, and very undeveloped in the frontal region. The forehead was low, and the head altogether appeared too small for the face. In the eldest girl the features were coarse; the expression was vacant, but usually amiable; the pupils were much dilated; the saliva flowed continuously out of the half-opened mouth: and indeed her general appearance was that of an idiot, though, in point of fact, the intellect was very fairly developed. The faradaic excitability of the facial muscles was decidedly increased; the galvanic was normal.

The first diagnosis that suggested itself was complicated progressive muscular atrophy; but this was distinctly negated by the fact that the loss of power preceded, by some time, the atrophy. On the other hand, the symptoms coincided in all important points with Charcot's description of five cases of sclerosis of the lateral columns. The only deviations were that his patients were from twenty-six to fifty years of age, and that death took place in all within three years. This valuable paper concludes with two other cases, which are, however, imperfectly recorded, as they were only seen once.

CHVOSTEK ON EXOPHTHALMIC GOITRE IN A CHILD.—A case of this kind, interesting from its extreme rarity in children, is described in the *Klinik für Pädiatrik*, April 1876. The patient, a girl, aged twelve, was tall, slightly built, and somewhat anæmic. The exophthalmos, which had been noticed four weeks, was considerable; the sclerotic being exposed for two or three lines between the eyelid and the upper margin of the cornea. Latterly, vision had been indistinct for distant objects. The thyroid gland was markedly enlarged, its consistence soft. A distinct whizzing was perceptible to both hand and ear over the thyroid arteries, which, together with the carotids, appeared enlarged and unduly pulsating. There was said to have been no palpitation, but there had been occasional attacks of dyspnoea, accompanied by pain in the side. The heart's impulse

was diffused, its action violent. There was no murmur. An interesting feature of the case was that one or both ears sometimes became intensely red for a time. The mammae were very slightly developed. The girl had never menstruated, had lived nearly always in Vienna, was of cheerful disposition, and had always been healthy, though for the last two years she had complained occasionally of pain in the side and oppression at the chest, and was soon tired after exercise. The family history was good. During the short time the patient was under observation she was treated with the constant current, but without result.

BAUER ON A FATAL CASE OF INTESTINAL OBSTRUCTION DUE TO A FÆCAL CONCRETION.—Dr. Bauer relates the following case in the *Jahrbuch für Kinderheilkunde*, Band ix. Heft 4. A boy, aged eight, came under observation on May 26. His digestion had always been weak, but he had had no severe illness. For a long time he had been constipated, and the use of purgatives and clysters had produced much tenesmus and only small evacuations. The bowels were said not to have been properly opened since the preceding February. There had been no particular abdominal pain.

On admission, he appeared anæmic and excessively wasted; but not feverish. His strength was so much reduced that rectal examination was deferred for a day. The abdomen was very prominent, its superficial veins were distended; no distinct tumour was felt. On percussion, a muffled tympanitic sound was elicited over the whole left side.

No troublesome symptoms occurred during the day; but, on the next morning, he complained repeatedly of abdominal pain and fruitless straining. He received from the sister on duty two spoonfuls of castor-oil, the administration of which was followed immediately by excessive distress and dyspnoea ending in collapse, under which he sank at 8 A.M. The necropsy, twenty-eight hours after death, showed a very hard round faecal mass, of the size of the fist, situated immediately above the sphincter so as to form a valve, which must have been closed with each attempt at defæcation. No nucleus could be detected. The whole large intestine was greatly distended, and so elongated as to form an irregular zig-zag of six parts; the first descending arm (traced backwards) reaching from the epigastrium into the true pelvis; the second from the left axillary region to the right anterior superior spine of the ilium; the third from the fourth rib to the right iliac fossa. The rectum measured $6\frac{1}{2}$ inches in diameter. There was recent peritonitis of the parietal layer and of the posterior surface of the large intestine. The latter contained, besides altered faeces, a large quantity of fetid gas. The small intestine and stomach were healthy. The diaphragm reached on both sides as high as the second intercostal spaces. The lungs were much compressed. The left ventricle of the heart was strongly contracted; the valves and great vessels were healthy.

UNTERBERGER ON CIRRHOSIS OF LIVER WITH ASCITES IN A CHILD.—Dr. Unterberger reports (*Jahrbuch für Kinderheilkunde*, Band ix. Heft. 4) the case of a boy aged five, who was admitted on July 29, with extensive ascites of two months duration. The cause was unknown. His general appearance was good; the skin and mucous membranes were pale; the face not puffed; there was no sign of jaundice; he had slight double conjunctivitis. The

lungs were pushed up; at both bases there was a little tough rhonchus; above, harsh breathing. The heart's impulse was in the third intercostal space, three-fifths of an inch outside the nipple-line; there was reduplication of the first sound over the mitral area. Respiration 30. Pulse 110, small. The abdomen was greatly distended ($27\frac{1}{2}$ inches); there was an abundant venous network upon it and on the breast. The liver and spleen were not detected by either palpation or percussion. There was no œdema of the scrotum or lower extremities; no albuminuria. He had from two to four semi-liquid good coloured stools. His appetite was good. Diuretics and vapour-baths were ordered. On August 8, the abdomen was tenser, its circumference somewhat increased. Seventy ounces of clear, yellowish, slightly albuminous fluid were drawn off with the trocar. After the operation, the contour of the liver was distinctly perceptible. From the costo-xiphoid articulation to the free edge, it measured $3\frac{2}{5}$ inch, in the right nipple line it reached $1\frac{1}{4}$ inch, in the left $1\frac{3}{8}$ inch below the false ribs. It extended $3\frac{3}{8}$ inch to the left of the middle line. The edge of the organ was sharp; its surface on the right side was somewhat rough. The round ligament, the longitudinal fissure, and the fissure for the gall-bladder were all distinctly felt. The right lobe of the liver was not so well defined as the left, but was evidently not extensively enlarged. The spleen was felt one inch below the false ribs; its consistence was leathery. On Sept. 2, the fluid had re-accumulated. The abdomen measured $29\frac{1}{2}$ inches. The patient's general health had, however, improved. The stools were natural. Respiration 24; pulse 98. Ninety-five ounces of clear yellow fluid were removed. The left lobe of the liver had increased in size. The measurement from the middle line to the left border was now $4\frac{2}{5}$ inches; and from the costo-xiphoid articulation to the free edge $3\frac{3}{8}$ inches.

All went on well for some time. The patient ran about briskly; his appetite was good, and the motions normal. On Sept. 17, however, a change took place. Apathy set in with abdominal pain (especially around the punctures), vomiting and cyanosis. The patient died on the night of the 18th with symptoms of peritonitis.

The necropsy was made twelve hours after death. The left ventricle was somewhat hypertrophied; the valves were normal. The bases of the lungs were œdematous. The abdomen contained five pints of cloudy flocculent fluid. The peritoneum was injected; there were slight adhesions. The punctures were bright red. The intestine was catarrhal, and distended with gas. There was much fat in the mesentery and upon the stomach and small intestine. The liver measured 7.2 inches in length; 5.2 inch in height; 2.4 inch in breadth; the left lobe was 4.4 inches long. The colour was flesh red; the consistence, especially of the right lobe, was dense. The surface of the anterior border of the right lobe was covered with flat knobs from the size of a pea to that of a hazel-nut. The left lobe and lobulus Spigelii were quite smooth. The ligamentum teres was of the size of a finger, and contained much fat; its veins were obliterated. The gall-bladder was natural; its ducts were quite free. On microscopic examination, the left lobe and lobulus Spigelii showed new fibrous tissue between the individual cells. In the rest of the organ the fibrous tissue was fully formed. The right lobe showed, in addition, some points of telangiectasis. The spleen was 4 inches long, of

dark red colour and leathery consistence (spleen of congestion.)

The points upon which the author lays stress are: 1. The rarity of the disease in childhood, more especially when associated with ascites; 2. The rapid growth of the left lobe—one inch laterally in twenty-five days; 3. The noteworthy circumstance that in this case, as well as in the two described by Steffen, the right lobe was first attacked—the reverse of the order observed in adults.

RALPH W. LEFTWICH.

GIBNEY ON PERINEPHRITIC ABSCESS IN CHILDREN.—At a meeting of the New York Medical Journal Association, on March 3, (*New York Medical Record*, March 25), Dr. V. P. Gibney read a paper on perinephritic abscess in children, in which he reported and analysed the histories of nine cases. Of these, seven terminated in abscess with external opening, and two in resolution. The existence of that affection had been denied by some authors; and, excluding all cases in which the abscess had been clearly of a secondary character, only three cases had heretofore been placed upon record. The ages of the patients, in the cases reported by Dr. Gibney, were respectively, 8, $1\frac{1}{2}$, 6, 9, $3\frac{1}{2}$, $2\frac{1}{2}$, 6, 10, and 2 years. Six were females, and three males. In seven cases no exciting cause could be found. Six out of the nine gave no evidence of struma. In seven cases the abscess (including the three cases reported by others) were upon the right, and in five upon the left side.

The disease usually began with a rigor, followed by febrile symptoms, more or less severe, loss of appetite, general indisposition, lancinating pains, and the locality of the pain was perhaps not positively determined.

Constipation was always present. There were elevation of the shoulders, a disposition to stand with the body leaning forward, flexion of the thigh, pain in the region of the kidney, tenderness upon pressure, prone position, tumefaction, and, finally, fluctuation. These symptoms, associated with the fact that the attack was an acute one, were regarded as those chiefly to be relied upon in making a diagnosis. Dr. Gibney regarded diagnosis of perinephritic abscess in the very young child as impossible. The most prominent portion of the abscess in these cases was situated near the centre of the crest of the ilium, three or four inches to the right of the vertebral spinous processes. In one case the tumefaction in the right lumbar region was five inches in longitudinal, and eight inches in transverse measurement. In this case jaundice was present. Spasm of the psoas muscle was regarded as a notable symptom, and in the cases reported was relieved in a marked degree after the evacuation of the pus. The practical diagnosis of this affection from hip-disease was not always easy.

While studying some of his cases, Dr. Gibney had felt almost prepared to admit the impossibility of making a differential diagnosis between perinephritic abscess and caries of the vertebræ. But when a case came under observation in which were present rigors, fever, nausea and vomiting, constipation, loss of appetite, pain in the side, etc., and the attack acute, spinal disease was believed to be very easily excluded. In primary uncomplicated cases the prognosis was favourable, and the treatment consisted in attention to the general condition of the patient; and, as soon as fluctuation became distinct,

evacuating the contents of the abscess, either by means of the aspirator or bistoury. Dr. Gibney remarked that he had not derived any special advantage from injecting the cavity of the abscess after the pus had been evacuated.

SURGERY.

DENEFFE AND VAN WETTER ON THE PRODUCTION OF ANÆSTHESIA BY THE INTRAVENOUS INJECTION OF CHLORAL-HYDRATE.—The authors have brought together into a volume several papers read on various occasions before the Belgian Academy of Medicine. They begin by giving a brief sketch of the history of surgical anæsthesia in general, and of the various attempts which have been made from time to time to introduce remedies directly into the current of the circulation. M. Oré's experience in the treatment of tetanus by the intravenous injection of chloral-hydrate is then discussed. Lastly, they give a tolerably full account of thirty-four cases in which various operations were successfully performed during anæsthesia produced by this new method. Eight of these cases occurred in the practice of M. Oré himself at Bordeaux; the remaining twenty-six are original.

The following is a condensed description of the plan devised by M. Oré, and recommended by Deneffe and Van Wetter. The solution employed contains 10 grammes (1 gramme = about $15\frac{1}{2}$ grains) of chloral-hydrate in 30 grammes of distilled water. This solution is not unfrequently found to redden litmus paper, owing to the presence of a small quantity of free hydrochloric acid. It should always be tested and, if acid, should be carefully neutralised by the addition of a few drops of a solution of sodic carbonate. The injecting apparatus consists of a graduated glass syringe, containing when full about 24 grammes of the solution. The nozzle of the syringe may be fitted into an intermediate tube of metal which has a wire sieve in its interior, destined to prevent any solid particles accidentally suspended in the solution from entering the vein. This metal tube, in its turn, is adapted to a fine gilt cannula provided with a steel trocar.

The following is the mode of procedure. The syringe is filled with the solution, care being taken to exclude air-bubbles; the intermediate tube is then screwed on to its nozzle. The trocar, armed with its cannula, is introduced into one of the veins of the arm, which has been previously distended by bandaging the limb higher up. The trocar is then withdrawn, and the jet of blood from the cannula shows that the latter is in the vein. The bandage is removed, and the syringe connected with the cannula. Not more than half a gramme of chloral hydrate should be injected at each movement of the piston. When from four to five grammes have penetrated into the vein the patient usually complains of feeling very drowsy. The injection ought now to proceed very slowly; complete insensibility is usually attained when from seven to ten grammes

of chloral hydrate have entered the circulation. The business of injection should not be hurried; on the other hand, it ought never to last longer than ten minutes. When the full effect of the anæsthetic has been produced, the cannula should be withdrawn, and the puncture covered with a bit of plaster. The anæsthesia thus induced is absolute, and the muscular relaxation complete; the patient lies on the operating-table like a corpse. After an interval of time varying from twelve minutes to three hours, this state gives place to one of deep sleep, from which, however, the patient may be temporarily roused. This after-effect of the anæsthetic may continue for many hours, or even for two days; while it lasts the patient feels no pain, and is perfectly tranquil.

The following advantages are claimed for this mode of producing anæsthesia: 1. Absence of any preliminary stage of excitement; 2. Absence of nausea and vomiting; 3. Accurate graduation of the dose administered; 4. Absolute character of the anæsthesia and muscular relaxation produced; 5. Prolonged blunting of the patient's sensibility, which protects him from the influence of shock.

The disadvantages may be classified under two heads: hypothetical, and observed. Among the former, the authors place the risk of thrombosis and embolism, inflammation of the wounded vein, difficulty of producing insensibility, danger of prolonged stupor. Among the latter, they enumerate transient dyspnoea, occasional irregularity of the heart's action, presence of a small quantity of blood and albumen in the first urine passed after the injection (this occurred in two out of their twenty-six cases), and finally, the risk of fatal syncope. That this risk is by no means illusory appears from one of their own cases. A healthy man was about to be operated on for cataract; six grammes of chloral-hydrate had been injected; insensibility was complete; one of the lenses had been removed, and the surgeon was about to perform section of the cornea in the other eye, when the pulse and respiration stopped suddenly and together. An attempt was made to resuscitate the patient with the aid of galvanism; but the battery was out of order, and the other means employed proved ineffectual. The heart was found flaccid, and with all its cavities full of blood; there was no clot in the veins of the arms, none in the right ventricle or pulmonary artery. In short, death could only be attributed to cardiac paralysis.

This fatal result does not stand alone. The authors lost another patient, from whom an ovarian tumour had been removed under the influence of chloral anæsthesia. In this case, however, death occurred an hour and a quarter after the injection had been completed; much blood had been lost during the operation, and the authors are disposed to ascribe the fatal issue to exhaustion from hæmorrhage.

It is only fair to add that the dangers and difficulties, whether real or imaginary, of M. Oré's method, do not in any way damp the enthusiastic anticipations of M.M. Deneffe and Van Wetter; they look forward to a time when the injection of chloral-hydrate into the veins shall have supplanted the various methods of inducing anæsthesia which now divide the suffrages of the profession.

E. BUCHANAN BAXTER, M.D.

MAAS ON POLYPI OF THE MALE BLADDER.—Dr. Hermann Maas, of Breslau, reports in the *Ber-*

linen Klinische Wochenschrift, no. 4, 1876, three cases of benign polypoid growths in the bladder of the male. Vesical growths of this kind are very rarely found in the male, and, in consequence of the anatomical conditions of the urinary passage in this sex, both the diagnosis and the treatment of the affection are attended with much difficulty. The subject of the first case was a carpenter, aged fifty-three years, who had been much weakened by frequently repeated hæmorrhage from the bladder. The urine, when not tinged with blood, was clear and apparently healthy, and a large catheter could be passed into the bladder without any difficulty. Dr. Maas, acting on the supposition that there was some slight ulceration of the vesical mucous membrane, proceeded to wash out the bladder by injecting a weak solution of carbolic acid through a large double catheter. During this operation the outflow of the fluid from the bladder was suddenly arrested by the impaction in the eye of the catheter of a soft mass, which proved to be a mucous polypus of the size of a hazel-nut, and furnished with a short and broad pedicle. A second and smaller growth of the same nature was removed at the same sitting in a similar way. There was very little hæmorrhage after the removal of the growths, and the patient subsequently remained quite healthy, and free from a repetition of hæmaturia. The growths thus extracted presented under the microscope the ordinary appearances of mucous polypi. An investing coat of mucous membrane, thickened by increase of its connective tissue elements, surrounded a mass of connective tissue which had undergone mycomatous degeneration. Both the submucous tissue and the outer layer of thickened mucous membrane were traversed by numerous wide and thin-walled capillaries. The second case was that of a man aged thirty-three years, who at first was treated for a tight urethral stricture. After this had been gradually dilated to such an extent that a full-sized catheter could be passed into the bladder without difficulty, the patient had an attack of retention. An instrument was then passed along the whole length of the urethra, but it was not until after some manipulation that Dr. Maas succeeded in drawing off the urine from a much distended bladder. This fact led Dr. Maas to diagnose the existence in the bladder of some movable body which had a tendency to slip into the urinal extremity of the urethra, and to remain there until pushed back by an instrument into the bladder. As there were no indications of a calculus, it was thought that this also might be a case of polypus. A large single catheter was passed, to which was attached an arrangement of elastic tubing and a funnel, by means of which fluid could be injected into or withdrawn from the bladder at pleasure. After a few injections an elongated polypoid growth was caught in the eye of the catheter, and extracted as in the former case. This growth resembled in its microscopic characters the growths removed from the first patient. The result of this treatment was quite successful, and there was no further attack of retention. In the third case, the patient, who was thirty-eight years of age, had also suffered from urethral stricture, and frequently repeated attacks of retention, which could always be temporarily relieved by the passage of a small instrument. The stricture was fully dilated by Dr. Maas, but the attacks of retention were still repeated, and became more and more frequent. As these attacks could not be attributed either to vesical calculus or to spasm of the coats of the urethra, it

was thought that, in this as in the two previous cases, there might be a polypus in the bladder. Injections were made as in the second case; a small polypus with a long and thin pedicle soon stopped up the eye of the catheter and was then removed. The patient had no subsequent attack of retention.

Dr. Maas points out that, though one might be disposed to regard the forcible pressure of the bladder in consequence of urethral stricture as the cause of protrusion of small portions of the vesical mucous membrane in the second and third cases, this view is opposed by the anatomical condition of the mucous membrane at the base of the bladder, and by the fact that, whilst urethral stricture is a frequent affection, polypoid growths in the bladder are rarely met with. According to A. Förster, these growths may be caused by irritation of the inner surface of the bladder, as in chronic hyperæmia, catarrh, etc., conditions which were present in the last two cases. In none of these cases did Dr. Maas succeed in making out the presence of the tumour by instrumental or digital examination. The small size and the soft consistence of such polypoid growths account, he states, for this failure. The secondary affections and the impairment of function observed in the three cases were such as had been previously described by authors. In the first case there were spontaneous hæmorrhages, which usually came on after abuse of alcoholic drinks, and were probably due to turgescence of the tumours and rupture of some of the thin-walled capillaries during micturition. Sloughing of small portions of the mucous investment, regarded by Förster as a frequent cause of bleeding from vesical polypi, was not observed in any of the growths removed by Dr. Maas. The method of treatment by which one of these growths may be forcibly carried by an outflowing stream into the eye of a large catheter seems, on account of its simplicity and freedom from risks, to be preferable to the use of a noose, as recommended by Dieffenbach, Guillon, and Bardeleben. But as Dr. Maas allows, his plan can be carried out with success in those cases only where the polypi are small.

W. JOHNSON SMITH.

HENDRY ON AVULSION OF THE WHOLE UPPER EXTREMITY: RECOVERY.—Dr. George Hendry, of Zilwaukee, Michigan, relates, in the *Detroit Review of Medicine* for December, the case of Samuel Watson, who, on July 22, 1874, while putting on a belt in a shingle mill, had his left arm caught between it and the pulley, and carried round the shaft four times. The arm then gave way, and he was thrown to the floor in an unconscious state, in which he was picked up and carried to his boarding-house.

On visiting him, Dr. Hendry found that the arm had separated from the shoulder in a circular manner, as a coat-sleeve torn off by the seam, but leaving a mass of flesh and bone projecting from the shoulder. This proved to be the entire scapula, with the posterior inferior angle projecting forward and out of the opening left by the separation of the arm, the head turned backward, occupying the place of the superior posterior angle, carrying with it and attached to it about one-third of the humerus, separated from all its muscular attachments but the deltoid.

While Dr. Hendry was bringing the patient under the influence of chloroform, Drs. B. B. Ross and C. H. Sample arrived. Dr. Ross removed the scapula by cutting the few attachments which remained. He

then removed one and three-fourths inches from the clavicle, which projected out of the wound. The anterior of the wound was ground out and blackened by the belt of the pulley, the remaining part covered with sawdust, which was washed off, and the exposed lymphatic glands cleaned and left in place. The subclavian vessels were torn off outside of the clavicle, and had bled but little. They were secured by ligatures. Some of the nerves were separated from the spinal cord, while others hung down four or five inches. The wound was smeared with balsam of Peru, the integument brought together and firmly stitched. A compress of oakum, wet on one side with balsam, was laid on the wound; the whole chest was then tightly bandaged.

From the wound down the side of the latissimus dorsi there was an infiltration of air through the wound. Svapnia was given in place of morphia, in sufficient doses to quiet pain and induce sleep. Cold was applied around the wound and along the side by ice in self-sealing fruit-jars—nothing being at hand more convenient.

In eighteen hours the fever was high; pulse 150; he had delirium and restlessness. The whole side, from the wound to the crest of the ilium, was highly inflamed, presenting a bright red appearance. Quinine was given, one grain every hour, with egg-nog, beef-tea, and raw eggs *ad libitum*. The following day there was a slight improvement. From this time the symptoms gradually grew better, pain subsiding as suppuration advanced. There was some sloughing of the edges of the wound, which were removed as required, and carefully syringed with an aqueous solution of carbolic acid. All along the track of infiltrated air there was a profuse suppuration, requiring incisions at different points down to the ilium, from which were discharged shreds of cellular tissue and a greenish pus of very offensive odour. On the twentieth day the wound was healing well; but to facilitate it Dr. Hendry engrafted several pieces of skin, which all took well, filling up the wound in eighteen days. An injury of the hip was at the time overlooked, but he recovered from it. At the time of injury, he had just recovered from a fracture of the lower part of the tibia and fibula.

BUCK ON A CASE OF PERITYPHLITIC ABSCESS, PRINCIPALLY TREATED BY EXTERNAL OPENING.—In the *New York Medical Record* for January 15, Dr. Gurdon Buck relates a case of perityphlitic abscess occurring in Mr. J. M., aged twenty-six, a person of good constitution and regular habits. When he was first seen, on November 8, he was suffering from very severe pain in the right iliac region. The abdomen was supple, but extreme tenderness on the slightest pressure existed over a spot that could be covered with the thumb at a point three fingers' breadth distant from and to the inside of the anterior superior spinous process of the right ilium, and on the same level with it. Beyond this, the tenderness on pressure diminished. The daily record of the symptoms is given by Dr. Buck up to November 19, when he met Dr. Alonzo Clark and Dr. Markoe in consultation, with special reference to an operation.

The precise seat of greatest sensitiveness under digital pressure was once more determined and located, as it had uniformly been, by daily repeated previous examinations, midway on a line between the umbilicus and the anterior superior spinous process of the right ilium. After complete anæsthesia

and relaxation were produced by ether, the deep-seated outlines of the tumour were again confirmed by a more thorough palpation than had been admissible at previous examinations. At the point chosen upon the surface, a puncture was made through the skin with a bistoury, to facilitate the onward progress of a sharp-pointed cannula of the size of no. 1 bougie scale, which was advanced cautiously through the aponeurotic and muscular parietes of the abdomen to a depth of more than one inch, when pus escaped by the side of the cannula, and immediately afterwards through the cannula itself. The cannula, being held *in situ*, served as a guide, upon the outer surface of which a sharp-pointed bistoury was conducted into the cavity of the abscess, and the opening enlarged. At the same time the external wound was also enlarged by dividing the skin and underlying parts to the extent of nearly two inches. A dressing forceps was then introduced with closed blades, and withdrawn with the blades opened, so as to enlarge the entrance of the abscess. A free discharge of greyish foetid pus, without stain of bile, to the amount of more than an ounce, followed, together with an abundant escape of gas. A finger was next inserted into the wound to enlarge still further the opening and explore the cavity of the abscess, which was found to extend in every direction laterally beyond the reach of the finger; its opposite wall, however, was reached by the end of the finger, but nothing definite was ascertained by it. A plug of cotton-wick well greased was inserted, and left in the opening to maintain it free; and poultices were directed to be continued. In the evening, the patient was comfortable, and his pulse at eighty-four. Next day the plug was removed, and gave exit to a copious discharge of brownish matter, followed by thick laudable pus. The plug was thereafter kept in only during the day and left out at night. On the third day poultices were discontinued, and a dressing of simple cerate substituted. The abscess was injected with salt and water, and the injection was repeated on the two following days. On the fourth day a particle of greenish fecal matter, of the size of a split pea, was expelled with the injection. On the fifth, sixth, seventh, and eighth days small tufts of sloughy connective tissue were discharged, the suppuration continuing healthy and abundant. On the twelfth day suppuration no longer proceeded from the cavity of the abscess, but from the external wound alone, which was steadily filling up and contracting. The patient's general condition steadily improved, after the opening of the abscess, under the use of generous diet and the citrate of iron and quinine. On December 4 he was able to be removed to the house of a friend, and on December 17 the wound had healed, and patient resumed his out-of-door life.

The present case is the second in which Dr. Buck has successfully established an external opening in the abdominal walls for the evacuation of an abscess, by a modified procedure, differing in certain respects from the method originated and employed by Prof. Willard Parker in 1867, and repeated since by others.

FRANKEL ON A CASE OF URETHRO-RECTAL FISTULA PRODUCED BY THE FORCIBLE INTRODUCTION OF SOUNDS.—Dr. Edward Frankel, visiting physician to the Charity Hospital, New York, relates the following case in the *New York Medical Record* for January 8.

S. R., aged forty, a German, consulted Dr. Frankel last May for treatment of urethral stricture and cystitis. He stated that, aside from his venereal trouble, his general health had always been good. About fifteen years ago he contracted a gonorrhœa, which was neglected, and gradually subsided into a gleet discharge; about twelve years ago symptoms of stricture developed, for which he was treated by dilatation by various physicians. For ten years he has been in the habit of passing a no. 10 English sound at irregular intervals. About one year ago the stricture became very narrow, and cystitis developed, and he placed himself under the care of a physician, who used to pass a no. 12 English sound, and injected the bladder. Much force was used at each introduction, and the patient suffered much pain, and lost blood. The cystitis and trouble in passing urine became very much aggravated.

When Dr. Frankel first saw the patient, he was very nervous and feverish. He had had no sleep for several nights on account of having to pass urine about every half hour, and micturition was accompanied by severe pain in the perinæum, which radiated towards the back and right hip. A no. 12 sound was obstructed about half an inch in front of the bulbous portion of the urethra, and also at about the membranous portion. All attempts to pass this stricture by various instruments failed, the instruments showing a tendency to deviate toward the right, and there was evidently a false passage here. While the patient passed urine in a very small forked stream, a considerable portion of it came through the anus. Rectal exploration with the finger revealed a round depression, which felt like ulceration, immediately in front of the prostate, and about three-quarters of an inch in diameter. A no. 9 sound introduced into the urethra could be made to pass from about the membranous portion to the right into a false passage which led into the rectum. The patient was ordered warm hip-baths, poultices to the hypogastrium and perinæum, and opiates. The bowels were moved freely. The urine contained much pus; no casts were discovered.

On May 18 perineal section was performed in the usual manner. It was ascertained that urethro-rectal fistula had been caused by forcible sounding and the establishment of a false passage. The patient rallied well from the operation; he slept well and regained his appetite.

On June 28 the rectal opening of the fistula, around which considerable ulceration had taken place, was discovered to be situated about $1\frac{3}{4}$ inches from the anus. By means of Sims's probe, bent at a right angle for about an inch from its extremity and coated with nitrate of silver, the fistula was cauterised once every five days. Rectal examination on September 8 revealed that the fistula had very much diminished in size, and now appeared as a valvular opening, with soft and granular edges; it measured about half an inch transversely. Cauterisations were made as before, and cold sitz-baths and perineal douches were continued at home.

Towards the middle of October the fistula had not closed, and flatus continued to pass, sometimes by the meatus and sometimes by the small aperture in the perinæum. Dr. Frankel decided upon closing the fistula by means of sutures; and on October 20 the patient, being etherised, was placed on his left side; the sphincter ani was first thoroughly stretched by the thumbs, and then a two-bladed rectal speculum was introduced. A no. 16 sound was passed into

the bladder, so as to render the fistula more prominent in the rectum. By means of a curved pair of scissors, such as are used in the operation of staphylorrhaphy, the blades being bent at right angles to the handle, the edges of the fistula, which were raised as much as possible by a Sims's tenaculum, were freshened, and then three fine silver wire sutures were introduced, according to the method of operating for vesico-vaginal fistulæ. The patient had opiates to cause constipation. The operation was not followed by either fever or pain, he slept well, and there was no disagreeable sensation in either the rectum or bladder. The result was successful.

SYPHILOGRAPHY.

BOYLAND ON THE TREATMENT OF VENEREAL DISEASES BY SALICYLIC ACID.—Dr. Boyland (*American Journal of the Medical Sciences*, October 1875), recommends the employment of salicylic acid in the treatment of gonorrhœa, phagedæna, balanitis, posthitis, etc., as being diseases of parasitical origin and nature. He employs a solution of one part of acid to 100 parts of water for urethral injections and for lotions; and, in long standing cases of gleet, uses a concentrated solution of one part to five, injected by means of Guyon's graduated stem-syringe. Chancres are first freely cauterised and then dressed with charpie soaked in the one to 100 solution, and frequently changed. Suppurating buboes are opened under salicylic spray, and dressed antiseptically with

the one to 100 solution. Dr. Böyland also recommends the internal administration of the acid in addition to the local treatment.

FOURNIER ON EPILEPSY AS A SYMPTOM OF CEREBRAL DISEASE IN TERTIARY SYPHILIS.—In a course of lectures delivered at the Lourcine in Paris (*Union Médicale*, 1875, pp. 529, 618, 681, 717), M. Fournier lays down the following rules regarding the occurrence of epilepsy as a tertiary syphilitic affection. Epilepsy showing itself for the first time in an adult over thirty years of age, previously in good health, may, in nine cases out of ten, be set down as due to syphilis. The disease may manifest itself either as a true epileptic seizure, or under one of the milder forms known as the *petit mal*. The first seizure is followed at an interval of some weeks or even months by a second similar one, to be repeated at a somewhat shorter interval; the fits subsequently recurring more and more frequently, until there may be one every day. In the early stages, the patient remains in his usual health between the seizures; but later on, other symptoms of cerebral disorder show themselves. Thus, there is more or less gradual impairment of memory, followed by a curious state of mental apathy; the patient loses all power of mental application, and may finally become idiotic. The moral character is perverted and weakened; the patient is morose, and although usually tractable, becomes subject at times to fits of ungovernable temper, or even to maniacal attacks. He suffers from violent cephalalgia, is liable to vertiginous attacks, and may become aphasic; finally, localised paralyzes of either sense or motion may occur, frequently succeeded by more or less complete hemiplegia.

As regards the question of diagnosis, M. Fournier lays stress on the following points as indicative of the syphilitic origin of the disease:—1. Absence of the shrill cry which usually announces the outbreak of an epileptic paroxysm; 2. Occurrence of paralytic symptoms immediately succeeding the fit; 3. Incomplete or unilateral character of the paroxysm; thus there may be no loss of consciousness during the seizure, or one half only of the body may be convulsed, etc.; 4. The constant occurrence during the interval between the attacks of cerebral symptoms in some form or other, gradually increasing in severity. The previous history of the patient, as well as the age at which the disease first manifests itself, furnish most important data regarding the diagnosis, while the result of specific treatment should also be taken into account. W. A. MEREDITH.

CASPARY ON THE ANATOMY OF HARD AND SOFT CHANCRE.—Caspary (*Archiv für Dermatologie und Syphilis*, 1876, Heft 1) examined three indurated chancres microscopically, and believes that a histological difference can be observed between the two kinds of sore. In the indurated chancre there is a new formation of connective tissue, which in the case of the soft sore, on account of a continual process of degeneration, never develops.

The new tissue begins by a tense close network, which surrounds the cells, and develops into complete fibrillary bundles which cleave the new cell-formations.

DEAHNA ON THE INFLUENCE OF ERYSIPELAS ON SYPHILIS.—Dr. Deahna (*Archiv für Dermatologie und Syphilis*, 1876, Heft 1) states that a man,

twenty-seven years old, the subject of an extensive recent syphilitic exanthem, with affection of the mucous membrane of the throat and mouth, was seized with erysipelas attended with acute febrile symptoms. In seven days, all the manifestations of syphilis had disappeared. A second syphilitic eruption soon followed, but was much milder and left the part previously affected by the erysipelas free. In this condition a second attack of erysipelas supervened with moderate constitutional symptoms. In three days all traces of syphilis disappeared, and there was no relapse.

TAYLOR ON COMMUNICATION OF SYPHILIS BY VACCINATION.—In the *Archives of Dermatology*, vol. ii. no. 3, Dr. W. Taylor describes a case of syphilis in which the disease was conveyed to a child by a prison surgeon who vaccinated it with a scarificator, which had just been used in vaccinating a prostitute, and which was not cleansed before being used for the child. The contagion was supposed to be conveyed by the blood on the scarificator, as of the twenty persons vaccinated at the same time the only one who became syphilitic was this child who was vaccinated immediately after the prostitute.

MATERIA MEDICA AND THERAPEUTICS.

RUTENBERG ON THE REDUCTION OF FEBRILE TEMPERATURES BY THE INTRODUCTION OF COLD LIQUIDS INTO THE BOWELS.—In the *Deutsche Medicinische Wochenschrift* for May 13, 1876, there is an article by Dr. D. C. Rutenberg of Vienna, containing the results of experiments on himself, and the trial of the same method on two patients suffering from intermittent fever. He remarks that Simon led the way by his proposal to inject large quantities of water into the bowel. Simon's paper was published in 1872 in Langenbeck's *Archiv*, Band xv. (1872), page 122. [In a previous article on this subject, the translator has shown that both Simon and Hegar only revived a practice and method which had long been used in England and France]. Hegar's method of using an irrigator, or even a simple funnel and long tube, was published in the *Deutsche Klinik* for 1873, p. 73. It thus became possible to introduce water at various temperatures into the abdomen. The copious blood-supply and the warmth of that cavity seemed to promise a favourable result to attempts at influencing the general temperature in this way [see Liebermeister's 'Handbuch der Pathologie und Therapie des Fiebers,' p. 55]. The iliac vessels and their ramifications are at once most directly exposed to the cooling influence of the water injected. And then it was not unreasonable to suppose that the influence would extend not only to the intestinal and peritoneal vessels, but even to the aorta and vena cava inferior. And very lately Kemperdick of Kolmar, with the same view of 'cooling the blood in the abdominal cavity,' carried out this object in a patient suffering from typhoid fever, by introducing a bladder into the rectum, through which by means of an irrigator he kept up

a current of rather cool water (9° to 12° Réaumur = 52.25° to 59° Fahr.). The result appeared, however, to be that only the temperature of the pelvis was affected, and in one instance this bladder burst. (*Berliner Klinische Wochenschrift*, 1873, p. 112.) That large quantities of water could be introduced a long way up the bowel was not then generally known. It is not very easy to keep up a constant current in this way, since the return-tube or catheter could not well be introduced so far as the fluid itself, so that it would be difficult to ensure uniformity of temperature in this way; more particularly in the position of the patient lying on the right side, desirable for other reasons, we could scarcely expect the warmed water from the ileo-cæcal valve to find its way out to the anus. It therefore seems better to introduce the water as cold as possible, to allow it to acquire the temperature of the body, and then, after letting it

escape, to introduce a fresh quantity. The experiments of Dr. Rutenberg were made on himself in the winter of 1874-5. He says that the injection of iced water into his bowel was not the least unpleasant, indeed, he thought the bowels less disposed to contract spasmodically than when smaller quantities of water were introduced of the customary warmth. The temperature was taken in the mouth, the thermometer lying between the cheek and the gum, and being fixed by a head-band, in order that, when read by means of a lens, it might not be shifted. When it was gripped more than usually firmly, there was a slight but evident rise in the mercurial column, just as noted by Liebermeister in the axilla. The instrument was nearly all the time in the mouth, and no reading is given from less than ten minutes *in situ*. Talking, etc. was avoided for obvious reasons. The first table is as follows.

TABLE I.

Experiment	Quantity of water injected	Time of day	Temperature before experiment	Temperature immediately after	The same for each quarter of an hour afterwards				
I.	2.2 pints	6 p.m.	100.22° F.	98.24° F.	98.42° F.*	98.96° F.	98.96° F.	99.32° F.	
II.	3.08 "	10 a.m.	99.14° F.	96.44° F.	96.8° F.*	96.44° F.	96.98° F.	97.34° F.	97.52° F.
III.	2.2 "	6 p.m.	100.58° F.	98.42° F.	98.42° F.	98.6° F.*	98.42° F.	98.96° F.	98.96° F.

The temperature of the water was 32° Fahr. or only a trifle above. The injection lasted 20 to 30 minutes. When the fluid came away, a portion of it appeared to be retained. In the second and third experiments, after a rise there was a fresh fall, as if

the cooled water had entered a fresh part of the bowel. The asterisks show when the bowels acted. In the next three experiments the thermometer was not disturbed at all, and was read every five minutes :

TABLE II.

Experiment	Temperature of water	Quantity of water	Time of day	Temperature		Fahrenheit each successive five minutes									
IV.	41° F.	1.76 pints	4 p.m.	97.16°	97.16°	96.9°	96.9°	96.9°*	97.16°	96.98†	96.62°	96.26°	95.36°	95.1°	95.19°
V.	38.75 F.	17.5 ozs.	11.10 a.m.	96.98°	96.9°*	96.85°	96.85°†	96.45°	96.2°	96.2°	96.26°	96.26°	96.4°		
VI.	36.5 F.	17.5 "	4.10 p.m.	96.8°	96.9°	96.9°	96.98°	96.9°*	96.7°†	96.45°	96.08°	96.20°			

* and † signify the beginning and end of the injection. There was no action of the bowels until after the readings of the thermometer.

The prompt reduction of temperature by this method of introducing cold water is obvious at the very first glance. In the second experiment the temperature fell about 1.5° C. = 2.7° F. in twenty-five minutes only, during the operation of the fluid.

There is thus a striking contrast between this method and that of the cold-bath system, during which Jürgensen found that a cold of 9° to 12° (52° to 59° Fahr.) applied for twenty-five to thirty minutes only lowered the temperature of the body about 1.4° = 2.5° Fahr., whilst he had the greatest difficulty in inducing people to submit to such torture (see the *Archiv für Klinische Medicin*, Band ii. p. 334, etc.) Liebermeister also points out that cool drinks and clysters (of the latter he only gives one example) cool the body from within, whilst the first effect of cold baths is to slightly raise the temperature. Experiments IV. and V. show slight elevation of temperature, perhaps accidental. The reduction of the general temperature by $1\frac{1}{2}^{\circ}$ C. = 2.7° Fahr., during the injection of less than three pints of water at freezing-point, shows no increase of warmth production.

One great advantage of this method is, that, unlike that of cold baths, its action is not impeded by the corpulency of the patient.

As regards calorimetry, the actual abstraction of heat in the fourth experiment could scarcely be more than thirty calories. But the thermometer gives for the body a loss of $66 \times 0.83 \times 1.1 = 60.2$ calories (Dr. Rutenberg's weight in kilos *into* his warmth capacity or specific heat *into* the fall in the thermometer) in thirty-five minutes; whilst we could only expect one of $\frac{30}{66 \times 0.83} = 0.547^{\circ}$ C., or a fall of

0.9846° Fahr. or less than 1° Fahr. instead of 1.98° Fahr. He notes that a few seconds after the injections there were slight rigors. Dr. Rutenberg does not think we are justified in assuming that the thermometer (say in the cheek) registers the mean temperature of the body. Parts like the brain are probably reached but slowly by changes in temperature. As regards the trial of the method in disease, two observations are given, made by Dr. Rutenberg, on two strong young patients suffering from intermittent fever, during the last summer at Strasburg.

TABLE III.

Afternoon	First Trial. Fahrenheit	Remarks	Evening	Second Trial. Fahrenheit	Remarks
2'30	105'98°	At 2'35 p.m., first injection of about three pints of water at 34'2° Fahrenheit	7'20	103'46°	Injection of 2'6 pints of water at 34'2° Fahrenheit
2'45	105'44°	Action of bowels. Three more pints injected	7'25	103'46°	
3'	105'10°		7'30	103'82°	Discharge of fluid, and fresh injection as above
3'15	105'62°		7'35	103'55°	
3'30	105'44°	All the water returned	7'40	103'46°	
3'45	105'62°	Fresh injection of 1½ pints	7'45	102'92°	
4'	105'62°	All returned. 1½ pint injected again	8'15	102'56°	
4'15	105'26°		8'30	101'84°	
4'45	104'72°	As above	8'41	102'02°	
5'	104'36°		10	102'30°	

These tables show, in the first case, in which there was a strong rigor an hour before commencing the trial, a fall in twenty-five minutes of about $\frac{1}{2}^{\circ}$ C. = 1° Fahr. If we allow that but for the injections, the temperature would have risen 42° C. = 107° Fahr., we have here in $2\frac{1}{2}$ hours a reduction of 2° nearly Centigrade = 3° Fahr. In the second case, there is a slight temporary rise = 2° C. = 4° Fahr. nearly after the first injection. The rigors in this case had occurred at 2.30 noon. Dr. Rutenberg notes that the same thing has been noted in health. He justly says that in the later stages of typhoid fever, the ulcers in the bowels might render it dangerous to inject very large quantities of water. [The translator has to regret that the Centigrade and Réaumur scales are so oddly and almost inextricably mixed up together in this article, that he has had great difficulty in making sure which was meant in any particular line. He believes, however, that his rendering will be found correct. Dr. Rutenberg appears not to have seen the papers of Dr. Wilson Fox and others on the use of tepid baths in very high temperatures. There can, however, be no reasonable doubt that the method of injecting iced water, or very cold water advocated here, is likely to be of great service in suitable cases. In two cases of hæmorrhage in enteric fever, and in two others of the same event in dysentery, the translator used this method with success.—*Rep.*]

W. BATHURST WOODMAN.

MEYER ON THE SOPORIFIC ACTION OF LACTATE OF SODA.—Dr. L. Meyer gives in Virchow's *Archiv* (Band lvi. Heft 1) the results of his inquiry into the validity of Preyer's hypothesis that sleep may be induced by the production of fatigue-products in the body (*Centrablatt für die Medicinischen Wissenschaften*, no. 35, 1875). To this end lactate of soda is administered. It is a clear yellowish-white syrup of sp. gr. 1'325 of pleasantly acid taste.

The cases experimented upon were various incurable diseases of the sexual and nervous system, all in females. All had been accustomed to a continual or occasional administration of morphia. The lactate was first administered subcutaneously, 0'6 grammes two or three times daily. The result was not encouraging. The injection caused pain in the part, and nausea or vomiting, without producing sleep or even ease. A larger dose by the mouth, 10 to 15 grammes, gave better promise. Some still had nausea or vomiting, but all got some relief from pain. It was afterwards found necessary to vary the administration of the drug, according as it appeared to

act upon the nervous or digestive system in particular cases. Sometimes it was combined with small doses of morphia. By means of this discrimination the effects were much more satisfactory. Preyer advises that the salt should not be kept as a syrup, but made when wanted by adding lactic acid to carbonate of soda (10 or 15 grammes of the latter are first dissolved in warm water, and lactic acid added till neutralisation is effected). The solution may then be given as a drink with milk and sugar, or with extract of beef. Meyer concludes that the value of the drug, so far as his observations go, is shown in the diminution of the requisite dose of morphia. If the lactate be given, the quantity of morphia required is much less, and so far it is of value. Latterly, at Virchow's suggestion, lactic acid alone has been given with results quite similar to those where the salt was given.

JAMES F. GOODHART, M.D.

GUBLER ON THE THERAPEUTIC ACTION OF HYDROBROMATE OF QUININE.—M. Gubler has made successful trials of hydrobromate of quinine injected hypodermically in intermittent fever (*Paris Medical*, May 4, 1876). The dose of eighty centigrammes given in three days sufficed completely to cut short the attack. The injection given two hours before the attack served to hinder its arrival. The facts communicated by M. Seulez (of Romorantin) completely confirm the rapid action of this new salt of quinine. He injected each time eighteen centigrammes of the hydrobromate of quinine dissolved in water slightly alcoholised.

GRZYMALA ON THE TREATMENT OF HYDROPHOBIA BY THE XANTHIUM SPINOSUM.—In a letter addressed to M. Gubler (*Paris Medical*, April 20, 1876), Dr. Grzymala points out the infallible properties of the xanthium spinosum in the treatment of hydrophobia. This affection is very common in Podolia, where Dr. Grzymala practises, and in the many cases where that physician has been able to administer the xanthium sufficiently early, the rabic virus has always been neutralised. The remedy must be administered early, before the attack has declared itself. The xanthium spinosum, a plant common in the middle of France, is a sudorific, a sialagogue, and a feeble diuretic, which generally produces only one or other of these effects, and not all together. The temperature is quickly raised, and the circulation slightly quickened. Sometimes some headache, nausea, and vomiting supervene during the day. The appetite is generally increased. The dose for an adult is from sixty centi-

grammes of the dry powder of xanthium, repeated three times a day, and continued for three weeks. Children under twelve take half. Dr. Grzymala has cured in this manner a large number of persons and animals bitten by dogs manifestly mad, whilst other animals bitten by the same dogs and treated by other methods succumbed with all the symptoms of hydrophobia. W. DOUGLAS HEMMING.

VON LIEBIG ON THE CURATIVE RESOURCES OF REICHENHALL.—In this paper (*Aertzliches Intelligenz-Blatt*, April 25, 1876) Dr. G. von Liebig gives an account of the water which is used at Reichenhall for drinking, in lieu of a natural salt spring. It is artificially prepared by diluting the Edel well with water, and by charging it with carbonic acid. The water contains about 9 per cent. of salt, and may be regarded as an imitation of the Rakotsky of Kissingen.

It is unnecessary to enlarge on the well-known effects of such springs, but Dr. Liebig calls attention to what has been less observed—the direct assistance which they give to the digestion or the solution of articles of diet. He has repeatedly observed, in himself and in others, the relief afforded to the stomach by taking a moderate glass of the water, when it has been disordered by rich food or by nervous causes. The feeling of nausea rapidly disappears, and is succeeded by appetite.

The physiological reason of this is perhaps explained by Dr. O. Nasse; he found, in making experiments with ferments, that the power of the human saliva or of the pancreatic juice to convert starch into sugar was increased about 12 per cent. by the addition of common salt in small quantities. Heidenheim also found that the solution of fibrine in gastric juice is distinctly accelerated by the addition of only one-tenth per cent. of common salt or of carbonate of soda. This acceleration is not increased by the addition of a greater amount.

Another portion of the success of similar waters in gastric and intestinal catarrhs is to be attributed to the local action of weak solutions of salt on the mucous membranes. Dr. Liebig, following in the steps of what has been done at Soden, has studied the application of the Reichenhall water in cases of granular pharyngitis and of nasal catarrh. For local application, the water is either used as a gargle, or pencilled, or injected by a pulverising instrument. By a little arrangement, the breathing may be so managed, that the mucous membrane of the larynx is reached by the spray.

The inhalation rooms for pulverised salt water are also used at Reichenhall with much advantage in affections of the larynx, in bronchitis, and in chronic pneumonia, and patients express great relief from using them, although the theory of how they prove beneficial is by no means clear. Besides the salt present, the air of the inhalation room contains 10.15 per cent. more moisture than the open air, or that of the graduating houses. The two together seem undoubtedly to exercise a soothing action on irritation of the mucous membranes associated with dryness.

Besides this, there is undoubtedly an unusual development of ozone in the air near graduating houses; and, indeed, it has been observed in the neighbourhood of the pulverised water of ordinary fountains. Dr. Liebig has made experiments on the quantity of ozone, which he means to continue, and meantime only remarks that under ordinary cir-

cumstances no ozone reaction would be observed in a room filled with people, like the inhalation room, as people rapidly use up all free ozone; whereas his experiments show that the air of the inhalation room, though it was full of people, contained a larger amount of ozone than the best outside air, and thus seemed to produce more ozone than was required for consumption. But the whole subject requires further examination.

[The manufacture of a palatable salt water at Reichenhall by the aid of carbonic acid affords a hint for the employment of the Droitwich and other salt-springs in Great Britain.—*Ref.*]

J. MACPHERSON, M.D.

STARKE ON THE USE OF OLEUM ERIGERONTIS CANADENSIS IN THE TREATMENT OF GONORRHŒA. Dr. G. A. Starke, of Milwaukee, calls attention in the *Canada Medical and Surgical Journal* for May, to a remedy which he has been using for four years, in the treatment of gonorrhœa—the oil of the Canada fleabane (*oleum erigerontis Canadensis*), very briefly noticed in works on materia medica. The results in most cases in which he has prescribed the oil, the patient adhering strictly to directions, have been entirely satisfactory, and in some cases astonishingly so. In the majority of the cases the discharge ceased in from two to six days. He has only taken notes of its effects in what he considered true cases of gonorrhœa. After having administered some suitable purgative, generally saline, he then gives the medicine in doses varying from five to twenty drops, every two, three, or four hours, as judged most prudent in each particular case. He has also given the oil in several combinations. The diet is also to be carefully regulated.

MILLER ON REDUCTION OF ENLARGED SPLEEN BY THE HYPODERMIC INJECTION OF ERGOT.—In the *New York Medical Record* for April 15, Dr. J. H. Miller relates the case of a lady, aged twenty-eight, whom he found suffering from masked intermittent fever with great enlargement of the spleen, occupying the abdominal cavity from the extreme left to the middle of the right hypochondrium, and from the umbilicus to the epigastrium. Quinine, chloride of ammonium, and iodine, with iodo-croton liniment, were used without effect; and Dr. Miller therefore determined to use ergot. On February 6 he made the first hypodermic injection of ergot. He visited her again on the 7th, and made the second injection; and, although he did not find any diminution in the size of the spleen, yet he discovered a very sensible change in its character and consistency. On the 8th he made the third injection, and at that visit there was a very perceptible shrinking. On the 10th he made the fourth insertion, and found a very decided diminution in its size; and for four consecutive days he made injections with rapid and marked diminution. On the 14th it had almost attained its normal size. Thus, from the 6th to the 14th, that enormous spleen had almost entirely disappeared under the hypodermic use of ergot alone. On March 4 he found the spleen normal.

DOUBELIR ON THE ACTION OF MERCURY.—Dr. Doubelir, of St. Petersburg (cited in the *Gazette Médicale de Paris*) gives the following summary of the results he has obtained by experiments on the action of mercury.

1. Mercury is a cardiac poison.
2. Death when produced by mercury is due to paralysis of the heart.

3. Mercurial epilepsy is connected with uremic poisoning.

4. The theory according to which mercury increases the metamorphosis of the tissues is very probably true.

5. Mercury should be given in large doses in inflammatory diseases.

6. It should be given in small doses in chronic affections where there is exudation.

MCDIARMID ON THE HYPODERMIC INJECTION OF MORPHIA IN INSANITY. — Dr. McDiarmid (*Journal of Mental Science*, April, 1876) has published a most exhaustive paper on the application of morphia subcutaneously in insanity.

Pointing out the disadvantages of giving this drug by the mouth, Dr. McDiarmid reminds us that it runs considerable risk of being altered, and having its virtues impaired, by the gastric secretions, or by the constituents of food. Even if it have escaped the action of the gastric juice, and have passed into the blood (as all such crystalloid substances are supposed to do), it has to go the round of the portal circulation and pass through the liver-cells. And even if the hepatic structures have no effect on it, it may have a prejudicial action on them, just as alcohol and other substances have; while opium is well known to check the secretion of bile, an action which may not be desirable at a time when its other properties are useful.

We can accurately observe the amount of morphia introduced into the system subcutaneously, and we can also give a definite dose hypodermically to a patient who refuses to swallow medicine.

And, as is well known to experimenters, many substances produce their effect much more rapidly when given subcutaneously than when given by the mouth, and speedy action is frequently most desirable in insane paroxysms.

Dr. McDiarmid has treated melancholia, acute mania, and the excitement of general paralysis most successfully by this method. It was also found of great service in improving patients of incorrigibly dirty habits.

When morphia is long in being followed by sleep, warm baths, or a small dose of tincture of cannabis Indica (℥xx to xxx) may be advantageously used as adjuncts.

In a continuance of the hypodermic treatment, it is necessary steadily to increase the dose. The rate of habituation in the generality of individuals is estimated at gr. $\frac{1}{60}$ or $\frac{1}{60}$ a day.

Vomiting occurred thirty-seven times in 413 injections, and this symptom was observed to take place most commonly when the drug was administered in the morning (of thirty-seven vomitings, twenty-three occurred in the morning), about an hour after breakfast. Any disordered condition of the stomach invariably caused vomiting with morphia.

Of the means employed to check vomiting strong coffee was found the most useful. Its effects are, however, transient. But the combination of atropia with morphia was more successful. Two cases of melancholia—one of which had vomited after $\frac{1}{4}$ gr. and the other after $\frac{2}{5}$ gr.—were injected with $\frac{1}{4}$ gr. and $\frac{2}{5}$ gr. of morphia combined with $\frac{1}{60}$ gr. of atropia. In neither case did vomiting occur after this administration. The atropia and morphia together were given in the evening, whilst the doses of the opiate which caused vomiting were given in the morning.

In the insane, Dr. McDiarmid advises that morphia should not be employed hypodermically in persons labouring under heart disease, or exhibiting any symptom which indicates serious brain disease, general paralytics excepted.

In melancholic females, Dr. McDiarmid has found it best to begin with $\frac{1}{60}$ gr. of the acetate of morphia (equivalent to about 14 minims of the liquor morphiæ acetatis B.P.), not oftener than once in twenty-four hours, and he has never found it necessary to increase the dose beyond $\frac{1}{4}$ gr. In melancholic males the dose generally begun with is $\frac{1}{8}$ gr. once a day, and all the sedative advantages of the remedy are usually gained without going beyond $\frac{1}{4}$ or $\frac{1}{8}$ gr. In acute mania $\frac{1}{4}$ to $\frac{1}{3}$ gr. may be given for a first dose, and in robust individuals $\frac{1}{2}$ gr. may be administered with safety. In recurrent mania $\frac{1}{3}$ to $\frac{1}{4}$ gr. is all that is necessary to secure quiet sleep. In the paroxysms of chronic mania, $\frac{1}{60}$ to $\frac{1}{4}$ gr. has the requisite calmative influence. General paralytics require and bear the largest doses; and in one case Dr. McDiarmid increased the daily amount to $\frac{1}{2}$ of a grain.

It must be remembered that it is very rarely necessary to give the morphia hypodermically oftener than three or four times consecutively, and only once was it given on more than nine successive evenings.

Of all the hypnotics and sedatives employed in this investigation, morphia, hypodermically administered, was found the most certain and speedy, being successful 329 times in 394 injections, the proportion of failures being about 16 per cent.

Dr. Clouston's favourite combination, tincture of cannabis Indica (℥xl), and bromide of potassium (30 to 40 grs.), was given eleven times successfully—twice it failed. Dr. McDiarmid considers that it is no doubt a very certain form of sedative, but it unfortunately causes so much stupor, confusion of ideas, and such paresis of the motor nerve-centres (after sleep is over), that it is a very dubious remedy in frequent doses.

Chloral comes next to morphia as by far the most potent soporific, the failures being 26 per cent. Although an invaluable hypnotic, chloral has the great disadvantage of exercising no sedative action. Tincture of cannabis Indica was a much better sedative than chloral, but exhibited very little soporific tendency in ordinary doses. Dr. McDiarmid is of opinion that bromide of potassium is too unreliable a sedative to be used with much benefit in insanity.

These experiments were made with a solution of acetate of morphia in distilled water, acidulated with

a few drops of glacial acetic acid, and having any excess of acid neutralised by liquor potassæ. The site of puncture was over either deltoid, from convenience of access, and as being free from veins.

If we are to estimate a mode of treatment, writes Dr. McDiarmid, by its success in aiding the restoration of the brain to a healthy condition, then the hypodermic method was most valuable in acute mania. As a sedative its benefits were, perhaps, felt most in melancholia.

H. SUTHERLAND, M.D.

MENDEL ON THE CAROTID PULSE.—The application of the sphygmograph to the carotid pulse of insane patients has been studied by Dr. Mendel, physician to the asylum at Pankow, and the results of his observations are given in Virchow's *Archiv*, vol. lxvi. p. 251. The normal carotid pulse, which is short and tricrotous (*Pulsus celer tricrotus*), is found in a certain proportion of the patients, including both old and recent cases of mania, melancholia, paralysis, and dementia. In a second series, the long pulse of atheroma (*P. tardus*) is found both in the carotid and in other arteries; the patients are mostly elderly, suffering from paralytic dementia, and other forms of disorder accompanied by considerable trophic disturbances. In some cases of unilateral cerebral disease—e.g. hemiplegia—the carotid pulses are different on opposite sides, that on the side of the lesion giving an abnormal tracing. In a third series, the pulse, naturally tricrotic in the radial, is dicrotic in the carotid artery; this is to be ascribed to dilatation of the capillaries and small arteries of the encephalon, and is observed in certain stages of progressive paralysis. But the great majority of the insane, especially melancholiacs, have pulse-tracings in which one or both secondary waves are increased in size, or an additional wave is present. These alterations are referred to increased recoil from the aortic valves as a result of obstruction in the cerebral capillary and venous circulation; that they occur only in the carotids is explained by the relations and proximity of these vessels to the valves in question.

[The value of the tracings accompanying this paper is lessened by the want of any record of the pressure employed in each case.—*Rep.*]

RECENT PAPERS.

The Premonitory Symptoms of Paralytic Insanity. By Dr. W. Sander. (*Berliner Klinische Wochenschrift*, May 22.)

OBSTETRICS AND GYNÆCOLOGY.

DUGAS ON THE TREATMENT OF MAMMITIS AND MAMMARY ABSCESS.—Dr. L. A. Dugas treats these affections by bandaging. He describes his method in a paper read before the Medical Association of Georgia (*New York Medical Record*, April 1, 1876). To lessen the determination of blood to the mammae while inflamed, the child is to be suckled as seldom as possible, and gentle compression, sufficient to force out the blood from the distended vessels, and cool applications to the organ, are the proper remedies. He has devised a bandage which, he believes, combines all the requisites. It consists of cotton or linen shirting, about ten inches wide, and long enough to surround the thorax, and

to be secured in front by digitations similar to other 'many-tailed bandages.' This is to be applied from the axilla downwards round the chest and over the mammae, and to be tied in front of the sternum. It effectually compresses both organs, and can be loosened or tightened without any difficulty. The child may be nursed through an aperture for the nipple made in the bandage. As soon as the congestion becomes painful or threatening, the bandage should be applied with such moderate tightness as will relieve pain, and the treatment should be continued until the trouble has been entirely subdued. When suppuration takes place, the pus should be let out by the free use of the bistoury, and a linen tent renewed daily. There should also be an opening in the bandage opposite the incision for the escape of pus. This bandage is adapted to every stage of mammary inflammation. If too late to prevent suppuration, it will lessen the size of the abscess, and after an opening has been made for the escape of pus, it will bring together the walls of the abscess, and hasten the cure. One of its greatest advantages is that it relieves the patient of all pain as soon as it is applied, by removing the distension to which the unsupported tissues are subjected by the congestion, or by the accumulation of pus.

KÖBERLÉ ON THE DIFFERENTIAL DIAGNOSIS OF SUBPERITONEAL SEROUS CYSTS, AND OVARIAN SEROUS CYSTS, BY THE NATURE OF THE FLUID.—This is the title of a communication read to the Medical Society of Strasbourg by M. Köberlé (*Paris Medical*, March 30). The diagnosis rests on the presence or absence, in the liquid contents of the cysts, of albuminous compounds, albumen, metalbumen, and, above all, paralbumen. The last-named substance is the one which is found in the largest proportion. The albumen is precipitated by nitric acid, and the precipitate remains or even increases on the addition of acetic acid. The paralbumen is also precipitated by nitric acid, but the precipitate is redissolved on the addition of acetic acid. As for the metalbumen, it exists in these liquids in such small proportions that it may be left out of consideration.

Now the cysts of the broad ligament do not ordinarily contain any albuminous compound. The cysts of the ovary, on the contrary, furnish a liquid charged with albumen, and, above all, with paralbumen. The cysts of the Fallopian tube contain only albumen, and no paralbumen. Nevertheless, exceptional cases exist, where the reactions are less distinct, and even lead to error; there is no absolute rule. If the trocar give exit to a thick liquid or a greasy liquid holding detritus of epidermis and hair in suspension, the cysts certainly belong to the ovary. There are colloid and dermoid cysts which contain no albuminous compounds. The physical aspect of these liquids suffices for their diagnosis.

W. DOUGLAS HEMMING.

CHURCHILL ON SOME CASES OF RETAINED OVUM.—In the proceedings of the Dublin Obstetrical Society for March 1876, Dr. Fleetwood Churchill relates six cases of retained ovum, which, he says, are of not unfrequent occurrence, although he has no means of computing the comparative frequency of such instances. The diagnosis is not easy for several reasons; there are no ordinary symptoms of pregnancy, the patient may say she is 'regular,' that she has lately miscarried, or that she is certain she

is not pregnant. In all the six cases, the usual signs of pregnancy were absent. Hence Dr. Churchill thinks it justifiable, on the ground of diagnosis, to adopt what he believes to be the best mode of treatment, that is, the introduction of the sound and the administration of ergot. If the uterus contain nothing, but is enlarged from other causes, the sound and ergot will be harmless, nor will they interfere with such other treatment as may be indicated. As Dr. McClinton has observed, when the ovum is macerated or putrid there is rarely any hæmorrhage. One of Dr. Churchill's cases was an exception, and she was the only one who failed to make a rapid recovery. Dr. Churchill regrets that in none of the six cases can he fix, with any accuracy, the duration of time of the retention. In all but one, the membranes had been ruptured long before expulsion, but in none was there any fœtor of the discharges. In Case 1, the marked symptom was recurrent uterine hæmorrhage; ergot expelled the shell of an ovum; the fœtus was absent. In Case 2, there was enlargement of the uterus; the ergot expelled an ovum of near three months. In Case 3, there were no symptoms of pregnancy; the os was wide and granular; the sound was used, and a macerated ovum of two months escaped within twenty-four hours afterwards. In Case 4, there were no symptoms of pregnancy; the os was wide and granular; the patient was treated for endometritis; at the end of two weeks violent flooding supervened, which was arrested by plugging; it returned, ergot was given, and the next morning a macerated ovum of three months was thrown off. In Case 5, there were no signs of pregnancy; the patient suffered from a uterine discharge of pale red colour, appearing irregularly. The sound was passed through a wide os, and two days later a macerated fœtus of about four months was expelled. In Case 6, there was a tumour between the pubes and umbilicus; no fœtal heart-sounds were audible; menstruation was slight and irregular. While debating in his mind whether he would pass the sound, Dr. Churchill was sent for to the patient, and found a macerated fœtus of four months in the bed.

BURDEL ON 'TELLURIC CARDIAC NEURALGIA DURING PREGNANCY.—Dr. Edouard Burdel (*Annales de Gynécologie*, May, 1876), relates two cases of telluric cardiac neuralgia occurring during pregnancy. The first case was seen by Dr. Burdel the day before labour set in. He found the patient with a pulse so rapid that it was impossible to count it; it felt like a vibrating cord, and the heart-sounds were indistinct and tumultuous; the skin was warm and moist. As she was on the verge of labour, Dr. Burdel merely gave an anodyne sedative. The next evening Madame X. was delivered before Dr. Burdel arrived, and told him she felt at ease in every way. Dr. Burdel, however, on examining the organs of circulation, found that the same alarming condition of the pulse remained. In addition, she was seized with vomiting and purging, which Dr. Burdel, not having a hypodermic syringe, could not allay. The patient died the next day.

In the second case the same symptoms showed themselves fifteen days before term. Dr. Burdel, bearing the last case in mind, at once injected a solution of one gramme of sulphate of quinine in six grammes of brandy over the epigastric region. The patient immediately became more sensible; and after the sixth injection the pulse fell to 175. The patient

slept for an hour, and awoke with a pulse of 150. Next morning the pulse was 130; Dr. Burdel repeated the injection, and in the evening he gave two more injections, containing each 0·75 centigramme of sulphate of quinine. He could now distinguish the fœtal heart which had been inaudible the day before. The patient quite recovered, and was delivered at term, twelve days after Dr. Burdel's first visit, with the most happy result.

Dr. Burdel, in discussing these cases, remarks that where there is a telluric influence in the background, as there was in these cases, quinine in large doses may be given with marked results. Had it been administered in the first case, Dr. Burdel thinks the result would have been different. This condition has been mistaken for angina pectoris, embolism, etc. Dr. Burdel, in conclusion, says that quinine may be given in large doses during pregnancy with safety both to mother and child, and denies that it possesses the ocytotic action which has been laid to its charge.

PENROSE ON THE TREATMENT OF FACE-PRESENTATIONS.—The American supplement to the *Obstetrical Journal of Great Britain and Ireland*, April, 1876, contains a paper by Dr. R. A. F. Penrose on the treatment of face-presentations. The author believes that the act of rotation forwards of the chin, which is the critical stage in face-presentations, is not effected in many cases, merely from the absence of a *point d'appui* upon which to rotate. Supply this, and rotation takes place. The floor of the pelvis is the natural *point d'appui* upon which the face should rotate, but the face is unable in many cases to descend so far, and remains jammed. In these cases Dr. Penrose supplies the wanting factor in this mechanism by opposing the hand, the blade of a forceps, or the lever to the posterior cheek; rotation then takes place and the child is born. To illustrate this, he relates a case of mento-posterior presentation, where the most powerful uterine contractions had failed to propel the child through a roomy pelvis during a struggle of thirty-six hours. He introduced a blade of a forceps and held it firmly against the posterior cheek, the chin rotated 'at once,' and the child was born in less than five minutes.

GALLARD ON THE TREATMENT OF INTERNAL METRITIS.—Dr. Gallard (*Annales de Gynécologie*, May, 1876), in speaking of therapeutic agents introduced into the uterine cavity, remarks that they are almost useless if in a solid form, for they cannot reach the corners and dippings-down of the uterus; he therefore uses liquid injections only, and has hitherto confined himself to the three following—solution of perchloride of iron, tincture of iodine, and solution of nitrate of silver. He most frequently uses the perchloride of iron. Nitric acid he considers too dangerous to be injected into the uterus. These injections are administered by means of a series of caoutchouc tubes of different sizes, which fit on to a syringe graduated to measure the quantity injected.

Dr. Gallard selects a tube small enough to allow of a reflux of the fluid. Where there is merely a congestion or excessive vascularity of the uterus, he recommends cold hip-baths and cold vaginal irrigations.

If the mucous membrane be thickened and ulcerated and beginning to be covered with granulations, Dr. Gallard thinks it necessary to check its vitality by some caustic fluid, such as perchloride of iron. Where there are vegetations, either sessile or

pedunculated, the cervix must be dilated by laminaria digitata, and the vegetations scraped off with Récamier's curette.

FANCOURT BARNES, M.B.

BAUM ON A CASE OF OVIARTOTOMY PERFORMED DURING ASCERTAINED PREGNANCY.—A case of this kind is related by Dr. Wilhelm Baum in the *Berliner Klinische Wochenschrift* for March 27. The patient, aged nineteen, had been married two years. In April, 1874, she was delivered normally of her first child, but her abdomen remained large from that time. From the end of January, 1875, the menses again ceased, and the enlargement of the abdomen rapidly increased. At the end of May the legs became cedematous, and the respiration was so much affected as to produce orthopnoea. An examination was made on June 9. The abdomen was then enormously distended, having a network of enlarged veins on the surface. It was universally dull, except that, in the side position, some slight resonance could be discovered in the uppermost flank. Fluctuation was felt throughout. By vaginal examination, the uterus appeared to be enlarged, and the cervix somewhat open. A uterine souffle was heard, but no foetal heart sounds. A diagnosis was made of an ovarian cyst complicated by pregnancy and ascites. Paracentesis was performed, and a painful of viscid fluid removed. Some movable solid masses were afterwards felt on the left side of the abdomen. The cyst filled again very rapidly, and on June 25 the operation of ovariectomy was performed under carbolic acid spray, all the precautions recommended by Lister being observed. Anaesthesia was produced by bichloride of methylene, administered with Junker's apparatus. The incision through the abdominal wall was four inches and two-thirds long, ending two inches above the symphysis. Some ascitic fluid escaped as soon as the peritoneum was divided. The gravid uterus was then seen, overlapped by a large globular tumour. After one thin-walled cyst had been emptied, it was found that adhesions to the abdominal wall and omentum prevented its being drawn out. These were separated by the hand, and a number of smaller cysts, containing very thick gelatinous fluid, were then broken up, and their contents cleared out with the fingers. A long thin pedicle was found, and was fixed by Spencer Wells's clamp in the lower angle of the wound. Considerable bleeding took place from the abdominal wall, where the adhesions had been separated, and, after many catgut sutures had been applied, it was found necessary to use the actual cautery to stop it. The divided omentum was ligatured, and fixed in the upper angle of the wound. The wound was covered with protective and carbolised gauze, with a large pad of salicyl-wadding over all. The patient did fairly well for the first two days, the pulse ranging up to 120, and temperature up to 102° Fahr. On the evening of the second day labour-pains commenced, and the os was found dilating. Abortion followed on the next day, the pulse afterwards being 134, temperature 101.5° Fahr. The dressings, which had become soaked through, were changed on the second day, and the secretion was found to be free from smell. For several days the patient suffered from nausea and rather severe symptoms, the pulse ranging from 120 to 134, and the temperature from 101.6° to 103.65° Fahr. The piece of omentum ligatured separated on June 29. On July 1 and 2 there were

severe cramp-like pains, and the pulse, which had become moderate, rose again to 140, the temperature to 104° Fahr. This afterwards subsided, but severe vomiting occurred on the 5th and 6th. The pedicle was divided with scissors below the clamp on the 6th. On the 10th the patient got up for half an hour, but on the 11th the temperature rose again to 104° Fahr., and on the 12th inflammatory swelling was felt all round the cervix, especially to the left side. On the 19th this had become softened, and pus appeared in the urine. From this time she rapidly improved, and left the hospital on July 31. The author attributes the cramp-like pains and vomiting to tension on the pedicle produced by involution of the uterus, and recommends that in future the pedicle should be left longer in similar cases. He argues against the opinion of Professor Martin, condemning ovariectomy during pregnancy, on the ground that, in this instance, the pregnant condition caused the cyst to increase rapidly.

[Dr. Baum does not enter into the reasons which led him to choose the performance of ovariectomy rather than the alternative of first eliminating the pregnancy by the induction of abortion. It would seem clear from the history, that the patient was exposed to considerably increased risk from the occurrence of abortion very soon after the operation.—*Rep.*] A. L. GALABIN, M.D.

DEPAUL ON CARCINOMA OF THE CERVIX UTERI IMPEDING DELIVERY.—In the *Archiv der Gynäkologie* for February 1876, Professor Depaul relates circumstantially an instance of cancer of the lower segment of the neck of the uterus, which presented a mechanical obstacle to the dilatation of the os uteri, and thus to the accomplishment of delivery.

The pregnancy appeared to have lasted over ten months. Attempts at delivery occurred about the end of the ninth month, and lasted several days, severe hæmorrhage also taking place. The foetal heart sounds were audible at first, but soon ceased. Physometra ensued; the membrane ruptured spontaneously, and the right arm and shoulder presented. A putrifying foetus was extracted by disarticulation of the arms and subsequent turning. Physometra persisted, the gas being of a most offensive odour. Acute septicæmia ensued, and the patient died at the end of a week.

At the necropsy, rupture of the uterus was found to have occurred, most foul-smelling gas escaping from the abdomen when this was opened. The cancerous condition was confined to the lower segment of the uterus, the fundus being free; the vagina was also healthy. The foetus was found to be hydrocephalic. ARTHUR W. EDIS, M.D.

TOWNSEND ON A CASE OF EXTRA-UTERINE PREGNANCY.—Dr. Lover J. Townsend, of Adairville, Kentucky, describes the following case in the *Nashville Journal of Medicine and Surgery* for March.

Mary M., aged thirty-two, mother of two children, two years previously to the time of seeing her, felt all the symptoms of natural pregnancy, suffering no uneasiness, mentally or physically, until after the expiration of ten months, when there was cessation of foetal movement, followed soon by some local pain and tenderness over the entire abdominal surface. Later still she experienced sharp cutting lancinating pains, which created such intense suffering that her attending physician resorted to opium;

which was given for ten months, when one day, suddenly, she was assailed with a most terrible diarrhoea, which continued for many days, and during which time she passed, at intervals, *per rectum*, all the bones of a well-developed foetal skeleton, save the frontal, occipital, and parietal, which could be distinctly felt through the flaccid abdominal parietes. Three inches below the umbilicus there existed several cloacæ, discharging, continually, a very fetid pus. Around these cloacæ an induration of surface extended over three inches in diameter, which was the guide in laying open the foetal sac, resulting in the removal of the bones above mentioned. As a result of peritoneal inflammation, the foetal sac was evidently glued to the abdominal parietes and large intestine. Ulceration and perforation of the intestinal wall soon followed, through which escaped the foetal bones.

RICHARDSON ON UTERUS SUBSEPTUS.—In the *Boston Medical and Surgical Journal* for March 30, 1876, Dr. W. L. Richardson says that there recently came under his observation in the out-patient department of the Massachusetts General Hospital a patient in whom the vagina was normal, while there were two distinct and perfect ora.

Mrs. —, twenty-five years old, began to menstruate when thirteen years of age. The catamenia, which were regular, except when interrupted by pregnancy, lasted about three days. The first few hours of each catamenial period were accompanied by very severe pain. The patient was married September 17, 1871. In November she became pregnant, and was confined on August 6, 1872. The child, a boy weighing seven and a half pounds, was born after a natural and comparatively easy labour of twenty-four hours. Nothing unusual was noticed during the course of labour, except the fact that the first few pains were accompanied by the loss of considerable blood. At the time of the delivery the attending physician stated that the patient had a double uterus. The request for a subsequent examination to verify this opinion was refused. The catamenia did not return between the birth of the first and that of the second child (a boy weighing nine pounds), on July 20, 1873, after a normal labour of eleven hours. The attending physician, as in the first case, noticed the peculiar condition of the uterus, and subsequently asked for an examination, which was, however, refused. The catamenia returned once between this confinement and the birth of her third child (a girl of seven and three-fourths pounds), on September 13, 1875, after a somewhat tedious labour of thirty-six hours. The same diagnosis of a double uterus was made, and a request for an examination was again refused.

At the time of her visit to the hospital the patient was nursing this last child, the catamenia not having as yet returned. Her general health was excellent. She complained of nothing except constipation, and the dysmenorrhœa already alluded to.

Examination showed the vagina to be normal. At its upper extremity two ora could be distinctly seen, the right one appearing like the os of a woman who had borne children, slightly patulous, round, and with an irregular slit on one side. There was a small ulceration at one point. The left os was like that of a virgin. Between the two ora was a band of normal tissue measuring about a third of an inch in width. The sound could be readily introduced into the right os, and by it the length of the uterus

was found to be two and a half inches. On bending the sound slightly, it could be easily introduced into the left os. Sounds introduced at the same time through each os were found to have passed into the same cavity. By sharply bending the end of the sound, it could very readily be passed into one os and out at the other. There was no appearance of an inflammatory action having existed at any previous time in the region of the uterus, nor could the patient give an account of the history of any previous uterine disease. A digital examination made *per rectum* and *per vaginam* detected nothing abnormal in the size or position of the uterus. A physician, examining the case at the ninth month of pregnancy, and recognising the presence of the two ora, might reasonably have concluded that he was dealing with a case of double uterus, inasmuch as, there being but one uterine cavity, the uterine tumour must have occupied the median line, which would not be the case with a pregnant uterus bicornis or unicornis. An examination made in the non-pregnant state alone could reveal the true condition of things. It is worth noticing that in this case, as in one reported by Corazza, the right os was situated in the median line, directly opposite the centre of the uterus, while the left one was slightly to one side. It was doubtless owing to this fact that the three deliveries took place through the right os. The record of these cases is interesting as showing that a double os does not necessarily indicate any abnormal condition of the uterine cavity above.

In a case, therefore, in which a physician's opinion was asked with reference to the probable duration and mode of termination of pregnancy in a patient whose uterus had two ora, and whose pregnant condition forbade the use of the sounds, the knowledge of the occurrence of such a case as that just cited would materially alter the prognosis which might otherwise be given under such circumstances. The existence of a double os might also readily occasion an error in judging of the stage to which labour had advanced, if the physician should examine hastily one undilated os, without recognising the existence of a second os, whose dilatation was more or less completed. This very error was made by the physician who attended the patient, whose case has just been reported, during her first confinement. Examining the left os, he gave an opinion that labour had not yet begun, and would not probably begin for some time; while the truth was the first stage was nearly completed, and the child was born soon after the examination was made.

DERMATOLOGY.

KÖBNER ON LEPROSY IN THE RIVIERA.—Köbner (*Archiv für Dermatologie und Syphilis*, 1876, Heft 1) notes observations he made on patients in a leper asylum at San Remo. The forms of the disease corresponded with those described by Danielssen and Boeck. Many facts concurred to bear out the known hereditary nature of the affection as also to show that it is not contagious. Köbner criticises adversely the view of Professor Erasmus Wilson, that the disease described by him as morphœa is allied to leprosy, directing his arguments more especially against the opinions maintained by Kaposi, in so far as he has followed the English dermatologist. The affection described as morphœa he believes to be of a different nature.

GEBER ON THE ANATOMY OF LUPUS ERYTHEMATODES.—Professor Geber (*Archiv für Dermatologie und Syphilis*, 1876, Heft 1) found that the earliest appearances observable were a condition of dilatation and stasis of the capillaries in the papillary layer of the skin, with evidences of a diseased condition of the vascular wall. An infiltration of lymphoid cells which begins immediately around the vessels, extends into the surrounding tissue, at first in rows and afterwards in masses. Whilst the cell-infiltration increases, the connective tissue bundles degenerate and disappear, until only a fine reticulum is left.

By an extension of the diseased condition from the vessels of the papillary layer to those surrounding the sebaceous glands, hair-follicles, and sweat-glands, an exudation of cells takes place around these structures, which is followed by alteration of their constituent and secreting cells. Division of the nuclei of the cells of the vascular wall and of the nuclei in the corium, with an appearance of granular protoplasm immediately round the nucleus, is interpreted by Geber as affording evidence of proliferation.

[Professor Geber has thus, as is remarked by himself, come to the same conclusion as the reporter, regarding one fundamental point in this disease. Geddings, Neumann and Kaposi have taught that the disease primarily involves the glands of the skin. Professor Geber and the reporter have found that the disease takes its origin in a morbid condition of the capillaries, and that the glands are affected secondarily.—*Rep.*]

WALLENBERG ON A CASE IN WHICH THE HAIR AND COLOUR OF THE SKIN WERE PERMANENTLY AFFECTED AFTER SCARLET FEVER.—Dr. Wallenberg describes the case in the *Archiv für Dermatologie und Syphilis*, 1876, Heft 1. The patient was a man twenty-one years old, and the eruption was characterised by intense redness. The desquamation was also unusual, the rete Malpighii being left bare by the falling off of epidermic flakes as large as the palm of the hand, which were separated from the subjacent skin by mucous exudation. This stage lasted four weeks, and was followed by the loss of the toe and finger-nails, the hair of the scalp, beard, eyebrows, eyelashes, the hair on the sexual organs, and the fine wool-hairs of the whole surface.

The hair, when it grew again, was white like an albino's, and the skin was milky white with a shade of red. The patient had been previously of a dark complexion with dark brown hair.

The skin remained highly vulnerable, an attack of universal eczema having subsequently followed exposure to the direct rays of the sun in a hot summer day, and on another occasion eczema following the application of mercurial ointment.

WIGGLESWORTH ON A CASE OF FIBROMA MOLUSCUM.—In the *Archives of Dermatology*, vol. ii., no. 3, Dr. Wigglesworth gives with a photograph an account of a case of fibroma molluscum, in which he counted 1,193 tumours. The patient, a man aged forty-five, observed the first tumour fourteen years before. The distribution of the tumours was most marked on the upper portions of the trunk, the genitals, palms, and soles being entirely free from them. Another case is reported of a farmer, aged thirty, the entire surface of whose body was studded with minute subcutaneous growths, but whose most conspicuous deformity was hypertrophy of the subcutaneous cellular tissue and integument of the anterior and external aspects of the left arm. The thickened skin hung in heavy cedematous and overlapping folds, movable upon the fascia beneath, increasing in size from above downwards like a drapery sleeve. The skin of the part had been long abnormal, but had attained its present size (pendulous to the extent of several inches) within a few years. Dr. Wigglesworth prefers the term 'cutis pendula' to dermatolysis for such cases. The pendulous skin was removed, and the wound cicatrised.

OSGOOD ON THE TREATMENT OF ELEPHANTIASIS.—Dr. Osgood (*New York Medical Record*) gives a tabulated account of fifty cases of operation for elephantiasis of the scrotum performed in Southern China, all of which recovered. The table contains thirty-three cases of Drs. Müller and Manson, and seven by the author. Dr. Osgood attributes much importance to the use of Fayer's tourniquet as a preventive of hæmorrhage during the operation.

REPORTS OF FOREIGN SOCIETIES.

FIFTH CONGRESS OF THE SOCIETY OF GERMAN SURGEONS.

The following abstract of the papers and discussions at the fifth annual meeting of the German Surgical Association in Berlin, under the presidency of Professor von Langenbeck, is taken from the *Deutsche Medicinische Wochenschrift* for April 29, May 6, 13, and 20.

April 19. *The Antiseptic Treatment of Wounds in Military Surgery*.—Professor Esmarch of Kiel, in commencing a paper on this subject, said that every one interested in military surgery, and who at the same time regarded, as he did, Lister's treatment of wounds as one of the most interesting surgical topics of our time, must have a lively sense of the need for making it useful in war. This question, however, must be answered during peace; and it would have to be determined by means of the experiences and

conclusions of civil surgery, how the method was to be carried out and advanced both in the official and the voluntary treatment of the wounded. As regards military hospitals, he said, the antiseptic treatment was to be employed in them in just the same way as in civil hospitals. The only consideration was, how to secure well skilled attendants, and the necessary supply of material. It was the special duty of the voluntary societies to solve these problems. Another question was, whether Lister's method was applicable on the field of battle. Here, according to Esmarch, strict antiseptic treatment was impossible. But, if its full effect was only to be expected when it was strictly carried out, ought it to be entirely abstained from on the battle-field? Esmarch was not of this opinion, but had endeavoured rather, by means of modifications, to make the principles of the method applicable in these circumstances. It had already been observed, before the introduction of Lister's method, that the most severe injuries in war, such as perforating gunshot wounds of the bones and joints, might heal without suppuration and without fever, and run a thoroughly aseptic course. Esmarch remembered especially three cases of this kind. The first was one of shattering by gunshot of the thigh-bone, occurring in 1848. The patient was very carefully treated by Ross, of Flensburg, and the wound healed under Fricke's dressing without suppuration. Later on, Esmarch more rarely saw such cases; suppuration and ichorous discharges were more frequently met with. These were generally ascribed to splinters of bone and foreign bodies, which were extracted according to rule. A second case occurred at Idstedt. There were two gunshot wounds, one of the upper arm, the other a simple gunshot fracture of the thigh-bone. The wound of the arm healed without suppuration in three weeks. At the end of four weeks, ichorous discharge occurred in the thigh-wound, with pyæmia, which led to death. At the necropsy, it was found that in the arm, which had again become movable in consequence of the pyæmic process, the splinters of bone were united with the callus. The third case was observed on September 15, 1870, in a wounded man who was brought to Berlin. There was a gunshot fracture of the upper arm, which was put up in a plaster-of-Paris bandage. The wound was not dressed during the journey. In the barrack hospital, the plaster-of-Paris bandage had to be removed, and no splinters could be found. A number of similar cases illustrating the aseptic course of the most severe injuries had been observed by others, especially in later years; this Esmarch believed to be due to the fact that the projectiles were smaller, and penetrated to the bone with more force than previously. How far the employment of carbolic acid—which was already adopted before Lister's time—was concerned, was undecided. But what was formerly the exception had become the rule since the adoption of Lister's treatment. Esmarch could entirely confirm Lister's results, and especially Volkmann's, who had treated more than forty complicated fractures by the antiseptic method without one death. Why did putrefaction especially occur in gunshot wounds? According to Lister, the causes were, not the bullet or splinters, but the excitants of putrefaction. These might be introduced into the wound with the ball, or more frequently on pieces of uniform, dirty clothes, etc., and set up septic processes. Bullets, passing rapidly through the bone, were less likely to do this.

Another source of mischief on the battle-field was produced artificially. The ordinary examination of recent wounds with the finger was hazardous. Formerly, this was the general rule; and so was the removal of bullets and splinters on the field of battle. From an antiseptic stand-point, Esmarch was opposed to this practice. The first principle of treatment was, *non nocere*; and an offence against this was committed by the practice to which he referred. Who could answer for the surgeon's fingers being clean? On the contrary, nothing could prevent them from being soiled with blood and other matters, through which septic processes might be excited. It should be remembered how frequently constitutional syphilis was present without being readily detected; and what would be the result of introducing the blood of a syphilitic patient into another man's wound! Those severe gunshot wounds, which ran an aseptic course before the introduction of Lister's method, were probably those which had not been explored with the finger. At Düppel, at the three dressing-stations on the field, all the cases were examined according to the rules of art. Was this in reality necessary? Was it for the purpose of deciding whether there were splinters, bullets, or foreign bodies in the wound? Whether amputation ought to be performed at once, or delayed till the patient's removal to an hospital? whether resection should be performed on the field? According to Esmarch, such examination was called for only when there were distinct indications for it. In such a case, however, it must be carried out with the greatest care. He saw much less danger in not ascertaining in the battle-field whether there were bullets, splinters, or foreign bodies in the wound, than in making an examination which might lead to the introduction of excitants of putrefaction on the finger-nerve in the explorations. The extraction of substances from the wound might be deferred to the patient's arrival in hospital, where it could be done under antiseptic precautions. As far as regarded examination on the battle-field, the principal question was, whether primary amputation was necessary? Since the introduction of Lister's method the indications for this had been entirely changed; and on the battle-field surgeons had in reality only to deal with the removal of limbs shattered by shells, etc. For such cases, material for antiseptic dressing ought to be at hand. The indication in such wounds was clear, without the necessity of any exploration. The first dressing should be omitted rather than done with dirty fingers, dirty water, etc. Everything used must be clean, and clean meant aseptic. Charpie was fortunately condemned; instead of it, cotton-wadding and jute were used; but these must be disinfected. In the earlier dressings, carbolic acid was employed; salicylic acid had now partly taken its place. Esmarch had contrived a small packet of the materials necessary for the first dressing, to be carried by each soldier. He had lately constructed, for the dressing-case of the assistants, a small parchment pocket containing a small ball of salicylised jute in salicylised gauze. This was to be used for wiping wounds, etc.—Herr Berns, of Freiburg, made a communication on the results of antiseptic treatment in his surgical clinic. He said that the number of cases treated was small for the purpose of comparison. Mistakes had also been made at first, and they had only gradually arrived at carrying out the treatment entirely according to Lister's method. The condition

of the clinic at Freiburg as regarded space could not be called bad, yet it was not without fault. The results of the treatment appeared to be inferior to those met with in Berlin, Leipzig, and Halle.—Dr. Burchardt, of Berlin, spoke of a modification of Lister's treatment. He recommended the following details. 1. The substitution for the ordinary spray of a stream of vapour developed from a two-per cent. solution of carbolic acid. The advantages were stated to be that the wound and surrounding parts were kept dry, and that there was no irritation of the wound by the antiseptic atmosphere. 2. The use of a spirituous solution of shellac, to which ten per cent. of carbolic acid was added. This was more easily prepared than Lister's lac-plaster. Pieces of linen or shirting impregnated with it adhered to the skin as freely as good adhesive plaster, and fitted themselves accurately to all inequalities. Over several layers of linen thus prepared, tinfoil was placed. The dressing was cheap. A disadvantage of it was, that on account of the impermeability of the material the evaporation from the skin was obstructed, and thus erythema was produced if the dressing remained applied for a long time. 3. Prevention of the removal of the antiseptic dressing, even while drainage was employed. In cases where drainage-tubes had been used, bacteria had often been found in the discharge from the wound. This could be avoided by connecting the tubes with disinfected lax India-rubber bags. In dressing the limbs, the enveloping of the diseased part in very thin India-rubber membrane was to be recommended: this was to be attached by carbolised solution of lac, and the drainage-tube brought out at the lowest part. In cases where the tube had to be brought out over an elevated border of the wound, Burchardt recommended the use of a combination of two bottles as a suction-apparatus, in the same way as for removing pleuritic exudations.

On Cotton-Dressing and Tannin-Dressing.—Herr Graf, of Elberfeld, said that he did not intend to speak of the modifications introduced into Lister's method by Thiersch, Bardeleben, and Volkmann, with a view to its simplification, but of the cotton-wool and tannin dressings. The earliest notice of the cotton-wool dressing, as far as he had been able to ascertain, was by Professor Burggraeve, whose method was warmly advocated by Ravoth. It consisted essentially on the immediate application of splints thickly padded with cotton to the injured limb, and aimed especially at securing immobility without taking notice of any wound that was present. It was therefore not applicable to the more extensive injuries of skin and destructions of tissue, and was not used in injuries of the hands and fingers, for example. The most important and promising modification of this was the cotton-dressing designed by Hermann Schulte, and described by him in the *Medicinische Centralzeitung* for 1857, and the *Deutsche Klinik* for 1860. While Burggraeve allowed his splints to remain applied as long as possible, Schulte insisted on the examination of the wound after a time. He laid on the injured limb a layer of cotton-wool from $1\frac{1}{2}$ to 2 inches thick; this also covered the wound and was secured by a bandage. After this, splints lined with cotton-wool were applied. The cotton-wool and blood became felted and dried, or, if there were bleeding of moderate duration, the dressing became saturated with blood; the cotton-wool around the limb, however, becoming dry and only that over the wound remaining moist. This dress-

ing was changed after four or six days. If there were neither inflammation nor suppuration, and there were a firm scab, it was left alone and only the surrounding cotton-wadding was removed. If suppuration were present, the part was dressed with cerate, and plaster of Paris was applied, etc. The principle of Schulte's plan was, then, the methodical application of so-called healing by scabbing, extended to large wounds. The disadvantage attending the plan, that the dressings not unfrequently became saturated within the first few days with blood, led Dr. Graf to use a combination of cotton-wool with tannin. The side of the cotton-wadding turned towards the wound was covered with a layer of tannin as thick as the back of a knife, and the dressings were applied as already described. If there were but little bleeding, the scab formed was perfectly dry, and remained adherent from four to fourteen days (Dr. Graf had not allowed it to remain longer). If the tannin were used to arrest rather considerable hæmorrhage, there was generally on the first day a moderate exudation of yellow fluid (serum containing tannin) into the surrounding dressings, which dried either with or without the addition of more wadding. If the dressings became moist after some days, incipient putrefaction might be arrested by the application of dry wadding or the affusion of carbolised oil; or, if there were much moisture, the dressing was renewed. The dressing must, of course, be loosened if inflammation, pain, or fever set in. But even here, if no indication for removal of the scab were detected on inspection of the edges of the wound, it could be allowed to remain and be covered in with fresh wadding. If it were necessary to remove the scab, warm water or, better, carbolised oil, should be used. The wound would be found of a dirty brown colour, covered with particles of tannin: if there had been considerable hæmorrhage, a brownish pulp was sometimes found between the scab and the surface of the wound. In normal cases, where the scab was detached at the end of the first or in the beginning of the second week, it was easily raised by a spatula; and under it was found a surface, either healed or granulating, and only occasionally covered with pus. Dr. Graf pointed out the advantage of this treatment as a preventive of inflammation. Fever and inflammation were generally entirely absent; and hence the tannin dressing found its application even in cases where it was not necessary in order to arrest bleeding. In a work published last year, Professor Fleck of Dresden had given tannin a high place among disinfectants. With regard to the hæmostatic action of tannin, Dr. Graf referred to a case of spurious aneurism after ligation of the common carotid artery, related by Dr. Hofmann in the *Berliner Klinische Wochenschrift* for 1871, in which recovery followed the plugging of the sac with a tannin-tampon; other similar cases, such as a dagger-wound in the abdomen penetrating the external iliac vein close above the femoral ring, treated successfully in a similar way, had come under his observation before he brought the tannin and cotton-wool dressing into use in cases of injury of the palmar arch. The success attending this had led to the employment of tannin dressing in cases of injury of the hands or fingers by machinery; since 1860, he had treated far more than a hundred such cases, attended with injury of the bones. In none of the cases, if brought early under treatment, was there local traumatic disorder. Fever and pain were either absent or very slight. Nothing was

removed but loose and perfectly useless pieces of bone, skin, and tendon; everything else was left, even though it seemed certain that necrosis must occur, and it often happened that preservation of parts occurred beyond what was believed to be possible. After accurate adjustment, and the ligature of such arteries as could be easily reached, but without probing or exploring the wound, and without minute cleansing of the skin, the tannin dressing was applied, and the hand and fingers carefully fixed to a padded splint, and left at rest until the dressing became saturated. Any corrective operations that were necessary, with the exception of removal of necrosed parts that could be done without trouble, generally took place in the third week or later. There were no cases of primary amputation or exarticulation of the hand. In complicated fractures of the limbs, Graf had at first used Schulte's cotton-wool dressing in almost all cases; more recently, he had also used the tannin dressing, unless, from the great extent of the wound, its total closure by a scab seemed impracticable. Lately, he had procured the tannin scab with good result in parts left bare by the plaster of Paris bandage. The tannin dressing was very suitable in cases of amputation of the breast with a clean surface-wound. In cases of operation for recurrent disease, Lister's plan could not be carried out, as the carbolic acid spray was too irritant to the unhealed cicatrix; after desisting from the attempt, erysipelas set in. Two subsequent cases of operation for recurrent disease were, on the other hand, found peculiarly suited for the tannin dressing, as at the same time the subjacent suppurating points could be dressed several times daily in the ordinary way. After the removal of vascular tumours, in which the different vessels could be only partially tied, and secondary hæmorrhage was imminent, the tannin dressing was especially applicable where compression could be applied. Herr Graf had lately removed from the head an angioma of the size of an ordinary fist; the largest afferent arteries were first isolated and tied, and, after extirpation, seven arteries were ligatured. Hæmorrhage, however, continued, but was at once arrested by the tannin dressing, which was allowed to remain twelve days; after its removal, a smooth granulating surface, without suppuration, was found remaining. A large venous angioma of the forearm and hand was removed under Esmarch's method; tannin dressing was applied, and changed after nine days; there were only two suppurating points. There was no reaction, and healing was complete in three weeks. The method was not applicable in cases of operation involving large sinuous wounds, or especially in the greater operations. The crevices of the wound could not be disinfected, the secretions, having no free outlet, became decomposed; and here the superiority of Lister's method and of the open treatment of wounds became apparent. Besides its antiseptic properties, the cotton-wool and tannin dressing possessed the undeniable advantages of being unirritant, hæmostatic, simple, and cheap. Herr Graf held that, until something better could be found, the tannin dressing deserved a place in military surgery. The simple closure of a recent gunshot wound or stab by cotton and tannin would obviate hæmorrhage and sepsis during the first days of transport; the dressing could be easily examined and removed, and could do no direct harm. Trendelenburg had insisted on the importance of a dry scab for the purpose of resisting

putrefaction, and this object was met by the tannin scab.

The Open Treatment of Wounds.—Herr Burow, of Königsberg, spoke of the success which had attended the use of the open treatment in his private clinic. In twenty-nine capital operations, including twelve amputations of the thigh and seven of the leg, there were only four deaths; viz. in two of the thigh and two of the leg cases. In two of the cases, there was gangrene; a third case was one of multiple sarcoma; and, in another, gangrene set in after an attempt at forcible extension in a case of aneurism of the popliteal artery, and it was found that the femoral vein was obliterated. He also brought forward further statistics to show that Lister's method was not, in comparison with other modes of treatment, attended with such brilliant results as its supporters alleged. He attributed the success of his treatment to the punctual carrying out of the open treatment, as recommended by his father.

In opening the discussion on the preceding communications, the President, Professor von Langenbeck, pointed out what were the principal subjects that demanded attention. It had to be determined whether the antiseptic method was applicable in military surgery, and what preparatory work was necessary for this in time of peace. Langenbeck believed that there was no doubt that no absolute rule could be laid down; neither Lister's method, nor the open treatment, nor that by scabbing, was applicable to all cases. What wounds must be treated antiseptically at once? *i.e.* on the field of battle itself, for in the military hospitals any treatment could be applied. Ought operations to be performed under the antiseptic spray? If there were any wounds which demanded antiseptic treatment, they were injuries of the head and penetrating wounds of the joints. Another question was, whether in such injuries the parts should be at once rendered immovable, and whether immobility can be carried out along with the employment of the antiseptic method.—Herr Busch of Bonn said that for a long time he had followed Burow's plan of the open treatment of wounds, and had gradually gone over to Lister's method. He alleged, however, that, if a simple comparison of numbers were made, the advantages of the antiseptic method might not appear so evident. In the meantime, much depended on the mode of healing. While the antiseptic method was one of the fairest weapons in the hands of the surgeon, on the other hand it was a two-edged sword, to be used only by him who was sufficiently familiar with it. In many operations, such as those on the genital organs, he had not gone so far as Volkmann, but hoped to do so. In military surgery, he held that the antiseptic method was as yet not thoroughly applicable on the field. When new military weapons were discovered and approved, soldiers were exercised in their use for many years before they were employed in war. The number of surgeons sufficiently exercised in the antiseptic method was not large. Military surgeons must become perfectly acquainted with it in the hospitals; and the German military medical organisation did not favour this. So long, also, as the wounded were not treated by the surgeon who first applied their dressings, there was no security for the carrying out of Lister's plan. He denied that it occupied too much time. Much time was saved by Esmarch's plan of bloodless operation; and Dr. Busch could operate as rapidly under the spray as without it.—Herr

Hüter, of Greifswald, thought that the application of Lister's method in the battle-field was difficult. He made remarks on the necessity of drainage, and recommended the use of antiseptic irrigation.—Herr Trendelenburg, of Rostock, pointed out numerous objections to Burchard's plan, and showed an apparatus for the employment of Lister's method.—Herr Heineke, of Erlangen, insisted on the difficulty of carrying out Lister's plan in military surgery in cases of gunshot fractures which demanded strict immobilisation. The use of the interrupted splints recommended by Esmarch was of service in many cases, but was not always admissible.—Herr Volkmann, of Halle, said that strict immobilisation was not necessary under the antiseptic dressing. If the first dressing were carefully applied, it was sufficient to place all complicated fractures on a tin splint with a foot-board; neither suppuration nor swelling took place. Even in cases of resection of the knee-joint, he was no longer so anxious as before. Of twelve cases of this operation, not one died of traumatic disease; in forty-nine complicated fractures, he had not a single fatal case; and besides these, he had had thirty-three equally successful cases of osteotomy. Hence he no longer attached so much importance to permanent immobilisation. The careful application of the dressing certainly occupied much time, when one desired to be certain of the disinfection of the wound. His results in the treatment of gunshot-wounds were perfectly successful; an aseptic course was secured.—Herr Koenig, of Göttingen, said that in cases of complicated fracture the length of time that elapsed before they came under treatment was an important matter. In the course of half-a-day, sepsis might occur.—Herr Hüter had met with a case of injury in which gangrenous septicaemia was present at the end of twenty-four hours.—Herr Volkmann again insisted on the necessity of using carbolic acid and drainage. It was necessary to carry out the details of the antiseptic method most accurately and minutely. If anything were overlooked, an aseptic course could not be secured. Immobility was very well obtained by tin splints. In cases of resection of the hip-joint, complete immobility had been long ago procured by their use.—Herr Hüter said that, when immobilisation and antiseptic treatment came into collision, he renounced the former. Consolidation might be thus impeded, but life was not endangered. In many cases, such as resection of the elbow-joint, both would be used.

April 20. *On Secondary Hæmorrhage after the Employment of the Bloodless Method.*—Herr Esmarch, of Kiel, gave a description of the application of his method in an amputation. After the limb was enveloped in the elastic bandage, the operation was proceeded with if the limb were white, and did not again become red. Esmarch preferred the circular incision, as the arteries were cut transversely, while by the flap operation an oval opening was made in the vessels, and it might easily occur that the whole lumen of the vessel was not included in the ligature. The operation being completed, everything which showed a lumen, including veins as well as arteries, was tied. The compressing ring should be loosened suddenly, not slowly. The parts remained empty of blood for a time, but soon the surface of the wound became filled like a sponge. Irrigation with ice was at once employed. Esmarch recommended that there should always be a number of artery-forceps at hand, so that no time might be lost in the ligature of

the vessels.—Herr von Langenbeck remarked that the discovery of a means of preventing secondary capillary hæmorrhage would be as important as that of artificial bloodlessness. He had never met with secondary hæmorrhage from vessels ligatured with catgut. If it were possible to prevent capillary bleeding, every amputation wound might be brought to heal by the first intention. The choice of the method of operations depended essentially on the kind of treatment; it must be different when antiseptic dressing was to be applied from that practised when the open treatment was to be followed.—Herr Busch, of Bonn, said that everyone who followed Esmarch's plan must pay for experience. The long-continued constriction might lead to paralysis of the vessels. In a fatal case, the *post mortem* examination showed anæmia of the brain.—Herr Volkmann, of Halle, spoke of the importance of the antiseptic method in regard to secondary hæmorrhage. Capillary hæmorrhage immediately after the operation was to be arrested by the application of antiseptic compression.

The Application of Catgut Sutures to the Uterus after Cæsarean Section.—Dr. A. Martin, of Berlin, made a communication on this subject. Since Veit in 1873 recommended catgut suture of the uterus in cases of Cæsarean section, it had been used in five cases in the obstetric clinic in Berlin. Strong catgut threads were passed through the entire thickness of the uterine wall, and tied in triple knots; in all the cases the bleeding was arrested, and the uterus at once contracted firmly. One patient alone recovered. Two others died of peritonitis. One of these, operated on in consequence of narrow pelvis, died on the third day; the uterine wound was united and the sutures were entire. The other patient had suffered from carcinoma of the cervix and extensive infiltration of the pelvic viscera; she died on the sixth day; the uterine wound was healed for the width of a centimètre externally, but gaped widely internally. The fourth patient showed symptoms of internal hæmorrhage thirty hours after the operation, which was performed on account of narrow pelvis and cicatricial narrowing of the cervical canal and vagina. The effusion into the abdominal cavity was removed; but it again occurred in fourteen hours, and led to death. The catgut threads in the middle of the wound had become loosened, allowing the edges to gape widely. In the fifth case, internal hæmorrhage set in fifteen hours after the operation, from the effect of which the patient died in a few hours. The Cæsarean section was performed on account of extensive narrowing of the cervical canal. At the necropsy, all the knots of the catgut threads were found loosened. Having regard to these cases, and to the most recent experience in London, Prague, and Breslau, Dr. Martin considered that the use of catgut for suture of the uterus ought to be rejected. He recommended the use of silk sutures, which were to be left within the abdomen.—Herr von Langenbeck believed that catgut sutures were not applicable in operations for vesico-vaginal fistula, and that in general they would only be used when the operation and treatment were carried out on the antiseptic plan.—Herr Fischer, of Breslau, had used catgut successfully in the treatment of perforating wounds of the abdomen. It was very durable for suture of the intestine.—Herr Winkel, of Dresden, was very well satisfied with the catgut suture in the operation for vesico-vaginal fistula.—Herr Busch, of Bonn, had used catgut as an uterine suture in two cases, and was much pleased with the result.

The Causes of Death in Surgical Cases.—Herr Heineke, of Erlangen, directed attention to the contradiction among surgeons as to the cases of death occurring in their practice. To estimate the amount of this difference, he considered a grouping of the causes of death necessary. What events caused death in surgical patients? Internal diseases must be excluded; and deaths might also occur from unfortunate accidents, such as chloroform-narcosis. Of much importance, however, was the class of causes of death having a causal connection with surgical treatment; to these belonged all the diseased processes which the surgeon could avoid. In the surgical clinic at Erlangen, from May 1867 to January 1875, 3,081 cases were treated; of these 213, or 6.9 per cent. died, the mortality varying in the different years. Of the 213 deaths, six were due to internal diseases, and eight to accident.

On Regeneration of Bone, with Special Reference to the Formation of Callus.—Herr Maas, of Breslau, read extracts from a long paper on this subject. With regard to development, he remarked that in the bones the non-vascular cartilaginous layer already showed in general the form of the grown bone. The development of the spinal osseous tissue coincided with the formation of vessels. The first action of the vessels on the cartilage was calcification; the vessels penetrating into the cartilage opened up its cavities. Two vascular systems were to be distinguished, the persistent, to which was due the growth in thickness of the bone, and the endochondral, which converted the cartilage-cells into bone-substance and bone-corpuscles. As the lateral walls of the medullary cavity, after the original cartilage had been changed into bone, and partly absorbed, partly combined with the periosteal osseous layer, there was no further formation of osseous substance, while at the end of the medullary cavity the cells for the growth in length were furnished by the epiphysal cartilages. Absorption of the osseous tissue took place in the periosteal vascular system at the sides of the medullary cavity, in the endochondral system, at the external absorption-surfaces described by Kölliker, at the point where the arteries passed into veins. As regarded regeneration, Herr Maas showed that the periosteum could not be regenerated from the osseous tissue nor from the surrounding connective tissue, but only from itself. The marrow, which in general was capable of contributing to the formation as well as the absorption of bone, might, after its destruction in the medullary cavity, be simply reproduced, or the medullary cavity was found filled with bone. The necrosis of bone frequently observed in these circumstances depended either on a simultaneous extensive destruction of the periosteum or on septic processes, ichorous thromboses being formed in the vessels of the bone. The epiphysal cartilages were not reproduced when destroyed or excised. Callus was exclusively a product of the periosteum. It was developed from the wandering cells, which passed in great quantity into the deep layer of the periosteum. It was at first purely cartilaginous, and was changed into bone-substance by the vessels entering it. This took place most rapidly in the medullary cavity; yet, in the marrowless bones of birds, and in bones from which the marrow had been removed, the whole callus could be found in a state of cartilage at a certain time after fracture. The superfluous callus was removed partly through the medullary cavity, partly through the external ab-

sorption-surfaces. Herr Maas had used cinnabar for tracing the connection between the cells. His results were the following. Particles of cinnabar were first found in the wandering cells; then in the cartilage-cells and in the bone-corpuscles; and, if the research were carried far enough, a large quantity was found in the cells of the marrow.

Experimental Researches on Ostitis and Necrosis.—Professor F. Busch described some experiments which he had made in the following manner. He first bored a hole in the upper-end of a long bone, generally the tibia, and destroyed the marrow by means of a wire. He then bored another hole at the lower end; and, having passed a fine platinum or iron wire through the two holes, connected it with a galvanic battery and cauterised the medullary cavity. The results, according to the intensity of the cauterisation, were classed in four degrees. In the first degree there was not necrosis, but only acute inflammation. In the second degree, there was central necrosis. In the third degree, the heat destroyed the entire thickness of the cortical substance at the part where it was applied (penetrating necrosis); if the whole circumference of the bone were cauterised, total necrosis was produced. A fourth degree of heat destroyed the whole tissue of the bone. This was followed by putrefaction, which destroyed the animals within the first week, without any appearance of reaction in the bone.

Experimental Researches with Reference to Ovariectomy.—Herr G. Wegner, of Berlin, made a communication on this subject, of which the following is an abstract. The causes of death after ovariectomy are generally said to be twofold: shock immediately or a short time (twenty-four hours at most) after the operation, and peritonitis at any time from twenty-four hours to fourteen days. It is incorrect to explain death in the first series of cases by shock. If shock mean reflex paralysis of the heart through violent and sudden irritation of the peripheral sensory nerves, it cannot be said to occur in ovariectomy, as irritation of this kind does not attend surgical operations—to say nothing of the deadening of sensation by chloroform-narcosis. Nor can we regard as more correct the explanation given by some authors, that death is due to cerebral anæmia, occurring from the overfilling of the abdominal vessels. On *post mortem* examination, anæmia sufficient to account for the sudden interruption of the functions of the brain is not found, and on the other hand intense abdominal hyperæmia may be produced in animals without producing any essentially ill results. The cause of death in these cases is to be sought in the cooling of the body, which is unavoidable in operations of some duration where the abdomen is opened. If the abdomen of an animal (rabbit, dog, or cat) be opened by a large incision, and the intestines be exposed to a temperature of 59° to 64.5° Fahr., the temperature falls in the course of eight hours as low as 73.4° Fahr. A few hours later the animals die, the temperature having fallen to 64.5° or 66° Fahr. The cooling mostly takes place during the first two hours, within which time the animal may lose 12.5° Fahr. of heat. At this time the respiration and heart's action are slow and weak, the animal functions are greatly interfered with, the intestines are completely paralysed, and the serous membrane intensely hyperæmic. The hyperæmia is partly arterial and partly venous, in consequence of the failure of the peristaltic action, which is an important agent in propelling the blood along the veins. There is no

exudation from the serous membrane, either now or later. The cooling of the whole body is due in a small measure to the continued rest of the animal, but mostly to the direct loss of warmth through the opening of the peritoneal cavity. The loss of heat is also favoured by (1) the great superficial extent of the abdominal cavity (which in a woman is calculated approximatively to be equal to the whole surface of the body); 2. By the absence of a bad conductor of heat on the surface; 3. By the loss of latent heat through the continued exhalation from the moist surface of the peritoneum. This loss of heat, highly injurious to animals, may be supposed by analogy to be equally so in a case of ovariectomy. In all probability, the amount of cooling in the human subject is still greater, in consequence of the use of chloroform. Wegner found in a healthy young man, to whom chloroform was given for two hours, that the temperature fell from 99.5° to 95° Fahr. Further, if the ovariectomy be performed under Lister's antiseptic spray, there is another source of reduction of temperature. A body having a temperature of 59° Fahr., was found to be cooled in two minutes under the spray to 41° Fahr., and one of 82.4° to 66° Fahr. This is a matter of great importance, and indicates the necessity of avoiding all sources of considerable cooling, such as the spray and prolonged narcosis; and at the same time an endeavour must be made to restrain the unavoidable loss of heat by the use of bad conductors. Herr Wegner has been able to prevent the loss of heat in animals for eight hours, by the use of a warming apparatus; and he recommended the use of one in ovariectomy. No physiological explanation has as yet been given of the fact that in some cases there is no peritonitis after ovariectomy, while in others it is often the cause of failure. There must be some fundamental differences in the quality of the cases to account for the difference of results. To explain them, the physiological relations of the peritoneum, and especially its traumatic conditions, must be considered. The great point to be considered is the great extent of surface of the abdominal cavity; the next, the transudative power of the peritoneum. A third point is the absorbent power of the peritoneum. The peritoneum of a rabbit can take up in one hour from 2 to 8 per cent. of the weight of the animal of a watery solution (salt, artificial serum, etc.). In consequence of this abundant and rapid absorption, the action of plastic injected substances (such as morphia, chloral hydrate, and cyanide of potassium) is almost immediate. Distilled water, serum, solution of common salt, solutions of neutral salts, infusion of muscle, urine, and even bile, are absorbed without presenting any ill effect on the serous membrane, so far as its structure is concerned. Substances different in quality, and acting injuriously on the body, such as large quantities of common salt or iodide of potassium, naturally produce their toxic action very quickly. Air, either ordinary or after filtration through cotton-wool, may be introduced in considerable quantities for months into the abdomen of animals without producing harm. If the air be injected in quantity sufficient to produce much distension, the changes produced—thickening of the peritoneum, formation of indurations on the liver, spleen, and stomach, dilatation of the lymphatics, especially of the mesorectum—are to be referred to the enormous distension, not to the air. Oily fluids are absorbed, partly directly, partly in emulsion, partly encapsuled in small drops. Fluid containing

particles (such as Indian ink, cinnabar, carbon, starch, milk, blood, and pus) are absorbed when the particles do not exceed the colourless blood-corpuscles in size; larger particles are encapsuled. No exception is shown by fluids containing micrococci and bacteria. As regards the mechanism of absorption, there are essentially three processes. In materials different in quality, there is diosmose. The removal of masses of fluid is effected by filtration, and—as the most active factor—direct transmission through the wide stomata of the peritoneum of the diaphragm (and of the mesorectum) into the immediately subjacent rich lymphatic network. The thoracic and abdominal pressure also acts. The increase of the abdominal pressure by expiration forces in the fluid into the diaphragm; the reduced thoracic pressure sends it on and carries it through the thoracic duct into the venous circulation. Of special importance to surgeons is the behaviour of fluids capable of putrefaction when left in contact with air, according as whether large quantities of air be enclosed with them or not. Their decomposition appears to be more rapid and energetic in the abdominal cavity than in any other part of the body, and the development of low organisms is most colossal. The development of these is greatly favoured—as has been shown by other experiments made outside the peritoneum—by the constant motion to which they are subjected in the peritoneum by the peristaltic action. If abundant absorption take place, the fluid is carried with the organisms which it contains into the circulation; and death results from septicæmia, in both the chemical and the corpuscular sense of the word. The only exception to the putrefying fluids is blood, which, taken from a living animal, and injected (deprived of fibrin) with any amount of air into the abdomen, does not undergo decomposition. As regards plasticity, the peritoneum has the most marked tendency to healing by the first intention. The serous membrane produces new cells, which, finding abundant pabulum in the serous exudation, do not die (*i.e.* become changed into pus-cells) but continue alive, soon becoming changed into a tissue containing vessels. As regards this, wounds of the peritoneum must *à priori* be regarded as favourable. Small quantities of injurious materials are absorbed, before decomposition takes place; substances incapable of absorption are encapsuled, and the wound tends to close in the shortest time. There is not the danger of immoderate tension which is so much to be feared in wounds of the connective tissue, muscles, bones, and joints; the diaphragm acts as a moderator of the pressure. In fact, in wounds of the peritoneum, the ordinary results of excessive tension—necrosis, gangrene, venous thrombosis, phlebitis, and embolism—are entirely absent. It is quite different, and a peritoneal wound becomes more dangerous than one in any other part of the body, if decomposed fluids be present in or be introduced into the abdominal cavity. Very large quantities of injurious materials may under these circumstances in a very short time enter the general circulation, with most serious danger to life. In cases of bursting of abscess into the peritoneum, or of perforating wounds of the intestine, it is not the peritonitis but the septicæmia which is most dangerous to life. After these remarks, ovariectomy, the extirpation of a healthy ovary from an healthy animal, must appear *à priori* to be relatively without danger. This is confirmed by the operations ordinarily per-
